THE SURGERY OF THE POSTERIOR CRANIAL FOSSA*

By DONALD ARMOUR, C.M.G., M.B. TORONTO, F.R.C.S. ENG.

SURGEON TO THE NATIONAL HOSPITAL, QUEEN-SQUARE

(*Concluded rom p. 504.*)

Cerebellar Tumours

IN childhood cerebellar umours are about twice as mon as those in th cerebrum. In the first le, 70 per cent. f all tumours are subtenial; between 10 and 15 ears of age, the supratenial and infratentorial are qual in number; between and 45, only about 18 per cent. are cerebellar; after the age of 55, ceebellar tumours, excluding of the acoustic nerve are practically unknown. These tumours are usualy median in situation, at y rate primarily, and bulg into the fourth ventricle above. From the milline they spread in time alward, into one or other of the cerebellar hemi- . Some are visibl on the surface, while hers lie beneath it. Th may be solid, hard, or cellular tumours, or lgely cystic.

Medulloblastoma

Medulloblastoma is th common type of mid- tumour of childhod. "This term indicates at the cells represent an embryonic stage earlier in either the spongioblast r neuroblast" (Bailey). ey are composed of very ebryonic undifferentiated ls of neuro-epithelial origi and grow with extreme idity. That the medulblastomata take their gin from an embryonic "st" is made probable the facts that their cell are of a germinal and differentiated type, normly found only in the abryo, their occurrence so rly in life, their median sition, and their occasion appearance in twins. ey seem to be about th times more common males than in females.

It is fortunate that they at ot common tumours, for they are highly maligne, and are prone to widespread dissemination in t cerebro-spinal spaces. Being median in position, t lie over the fourth ctricle, from the posterior p of the roof of which ey usually take origin, and ject into the centre of the cerebellum. The tumou ends to mould itself in o the distended aqueduct Sylvius, and by its occlusion gives rise to a well- ked internal hydro- halus. While in the great jority of cases the r of the fourth ventricle rem s free from invasion the growth, in some case n; tumour appears to be adherent to it, either by ension through the tela or by metastatic implan en. Because of its seat of origin, the tumour tably deforms and distends the ventricle, and fr ntly projects down for some distance through the a men magnum into the spinal canal.

The histories of these cases a striking resemblance to one another. The ugural symptoms are early morning attacks of pe iting without any preceding nausea ("les tr pseudo-digestifs itiaux des tumeurs de la T postérieure" of rench neurologists), which u precede the onse f any neurological signs by d months. Hen e almost invariable history nc previous ap ectomy in these cases. th ually associated with these attacks tress upon the import-

ve
the
uous
con-
Blood-
may form
the connective

pital discomfort, due to a commencing hydrocephalus with increased intracranial pressure. These attacks may be intermittent at first, suggesting the re-establishment from time to time of a normal circulation through the iter. The head enlarges from separation at the cranial sutures, thus compensating for the increased pressure. Sooner or later the child becomes clumsy and falls more easily, and its gait becomes uncertain. Frequently a diplopia develops, and examination of the eyes reveals a papillœdema.

The final picture is pathognomonic: a young child with an enlarged head giving a cracked-pot percussion note, a cerebellar gait with ataxia more marked in the trunk and legs than in the arms, hypotonia, and suboccipital tenderness with, perhaps, slight retraction of the head. The extremities are usually equally involved, unilateral predominance of symptoms being unusual. Many of these children show a tendency to fall backwards. Nystagmus, more frequently than in other cerebellar lesions, is very often absent. Occasionally, these children suffer from Jacksonian cerebellar fits, in which retraction of the head and arching of the back are associated with flexion and supination of the elbows and rigid extension of the legs and pointing of the toes.

Out of 131 histologically verified gliomas at the Neurological Institute of New York, nearly 13 per cent. showed calcification visible on X ray examination. Of the 25 medulloblastomas in this group, visible calcification was present in three cases (12 per cent.). Radiography will often show absorption at the posterior clinoid processes, a result common in posterior fossa lesions which cause a block ith dilatation of the third ventricle. There may even be pituitary dysfunction from pressure on the pituitary body.

Lumbar puncture should never be performed in these cases, and if ventriculography be resorted to, it should be by direct po tap and not by encephalography. But d, especially ay facilitate the dissemination of the grow er or conne bro-spinal spaces giving rise to the con lcification. nonly known as "sarcomatosis of the m The same thing may result from the giomatous of the tumours operation, the neoplas er the head g scattered malforn cerebro-spinal spac are included three types of lesior spinal canal or be the telangiectases; (2) the ven of fluid over the ngiomas; (3) the arterial or arter as implantatior venous angiomas.

The *telangiectases* are small, mai capillary lesions, which do not give usually to any clinical symptoms. Acco ing to Virchow the floor of the fou ventricle is a favourite site for them, a in cases reported they are commonest the upper part of the pons. They are always confined to the pons, however, may be multiple in the cerebro-spinal nerv system. Whether these telangiectases are capa of developing into the other two forms is known.

The *venous angiomas* are divided by Cushing a Bailey into three anatomical varieties: the sim varices, the serpentine varices, and the racemose cirsoid type. Any of them may give rise to sympto suggestive of tumour, epilepsy being the common result of the lesion. They are usually unacco panied by papillœdema, though this has been pres

se arising in the fourth ventricle grow outward backward, compressing the cerebellum and cing an internal hydrocephalus by blocking the luct of Sylvius (Fig. 7). It has been suggested a considerable part of the non-obstructive cephalus found with tumours of the choroid s may be associated with the increased epithelial ce

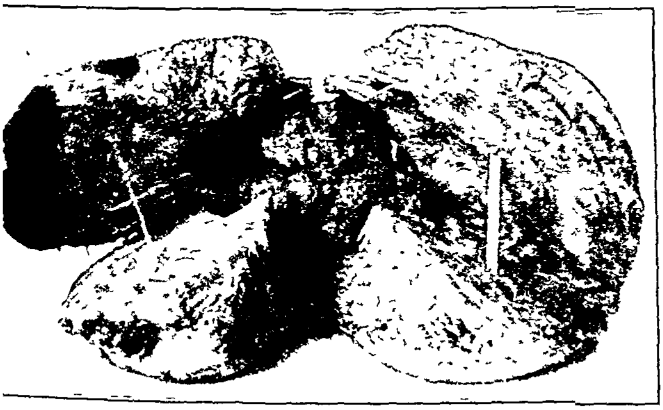
e papillomas of the fourth ventricle give rise to l symptom-complex of mid-cerebellar tumours. as t first, they give rise merely to symptoms ste with an increased intracranial tension due rnal hydrocephalus, without localising signs, often without papillœdema, or with only a slight of swelling ventriculography is especially l. The symmetrical dilatation of the lateral ricles and the filling of the third ventricle place structive lesion in the aqueduct of Sylvius. originating in the lateral recess of the fourth le, however, they may give rise to symptoms ting those of an "angle" tumour.

s been found that radiation of these tumours a marked effect in reducing their size and vascu- thus enabling them to be removed more easily ith a greater safety at the second stage of an ation.

Dermoids

the 39 intracranial dermoids reported in the ature, 15 were situated in the posterior cranial a, 13 being in the midline and 2 in the right bellar hemisphere. They are encapsulated ours, varying in size from a pea to a tangerine ge; oval, round, or hour-glass in shape; soft or cystic; with an opaque yellow colour. Like the ermoids they may have a pearly sheen. Their tents consist of sebaceous material, fat, cholesterol stals in varying amounts, and always hair (Fig. 8). presence of hair may be regarded as pathogno- onic of a dermoid or teratoid tumour. If infected e contents will consist of purulent matter.

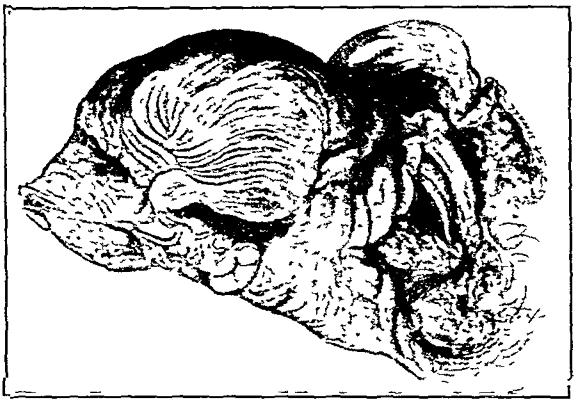
FIG. 7



pilloma of choroid plexus, fourth ventricle. (Museum, London Hospital.)

Microscopically the tissue is seen to consist of hree layers: a fibrous outer layer, a connective sue stroma, and an inner epithelial layer. In the ase of pial dermoids, the outer layer is continuous ith the pia mater, which is thickened, and is continuous with the connective tissue stroma. Blood- essels enter the tumour from the pia, and may form vascular layer between the pia and the connective issue layer. Boestrom lays stress upon the importance of the pia in the nutrition and growth of the anlage. Calcification and bony or cartilaginous spicules may occur in the connective tissue stroma, and be revealed by X ray examination.

FIG. 8



Dermoid cyst of the cerebellum. (Museum, Royal College of Surgeons of England.)

Intracranial dermoids are found at all ages, but the majority of the 39 reported cases have been in the first three decades (11, 5, 9). The sexes appear to be about equally affected. The tumour was single in 33 cases and multiple in 6. It was pial in type in 25 cases. Unlike the epidermoids the dermoids are never found in the cerebello-pontine angle. While other congenital anomalies are rare in association with the epidermoids, they are frequent with dermoids.

Unless the presence of such congenital anomalies arouses one's suspicions, it is not possible to make a pre-operative diagnosis of the presence of a dermoid from the neurological findings alone. Calcification in a tumour as shown by the X rays should lead one to keep in mind the possibility of its being a dermoid, especially if there is a bony defect over or connected with the area of the calcification.

Angiomatous Malformations

Under the head of vascular malformations are included three types of lesions: (1) the telangiectases; (2) the venous angiomas; (3) the arterial or arterio-venous angiomas.

The *telangiectases* are small, mainly capillary lesions, which do not give rise usually to any clinical symptoms. According to Virchow the floor of the fourth ventricle is a favourite site for them, and in cases reported they are commonest in the upper part of the pons. They are not always confined to the pons, however, but may be multiple in the cerebro-spinal nervous system. Whether these telangiectases are capable of developing into the other two forms is not known.

The *venous angiomas* are divided by Cushing and Bailey into three anatomical varieties: the simple varices, the serpentine varices, and the racemose or cirsoid type. Any of them may give rise to symptoms suggestive of tumour, epilepsy being the commonest result of the lesion. They are usually unaccompanied by papillœdema, though this has been present sometime after, first by symptoms of cerebellar involvement and then by visual disturbances. The long interval, which may run into months, between the onset of the paroxysmal headaches and the appearance of papillœdema is a very striking feature in these cases.

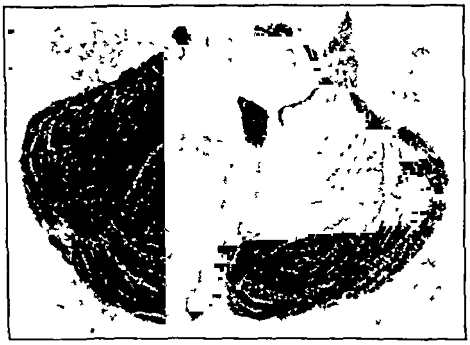
Tuberculoma

Nothing is so striking as the difference of the present-day frequency of tuberculoma, compared with that of twenty-five years ago. For instance, in Starr's statistics (published in 1908), of 300 brain tumours in children, 152 were tuberculomata (50·8 per cent.), of which 69 were in the posterior cranial fossa; while in 300 brain tumours in adults, 41 were tuberculous (13·6 per cent.), of which 19 occurred in the same region. In contrast with these figures, one finds that in the last 1000 verified brain tumours at the National Hospital, only 1 per cent. were tuberculous, and in Cushing's 1398 verified tumours, 26 were of that nature.

All statistics show the greater frequency of tuberculoma in the young—according to Gowers three-quarters of the cases are under 20 years and one-half of them under 10 years—and that their seat of election is in the posterior cranial fossa. Further, nearly all writers on the subject lay stress on the fact that the solitary tubercles of childhood show a marked predilection for the cerebellum and brain stem. This has led van Wagenen to raise the question whether the greater prevalence in young people, and especially of solitary tubercles, may not have something to do with the type of organism concerned in the process, whether bovine or human.

Occurring in the brain, tuberculomata form solid, firm, rounded masses, varying in size from that of a pea to that of a walnut, or even larger (Fig. 13). They do not infiltrate the brain tissue, but cause atrophy of it by pressure. They are mostly well-defined and shell out easily. They are often surrounded by an area of vascular engorgement, but as a rule there is no definite capsule. A capsule of fibroid tissue may be formed around them, however, if the mass ceases to grow or calcification takes place. The large solitary tuberculoma is a peculiar manifestation of tuberculosis in the brain "where the extension of the inflammatory process is allowed to proceed symmetrically, unhampered by planes of fascia or strands of connective tissue" (Boyd). They usually occur without apparent connexion with the membranes, differing in this respect from gummata. When, however, the tumour reaches the pia mat latter becomes thickened and often adhe the dura. Very occasionally they grow fr dura itself.

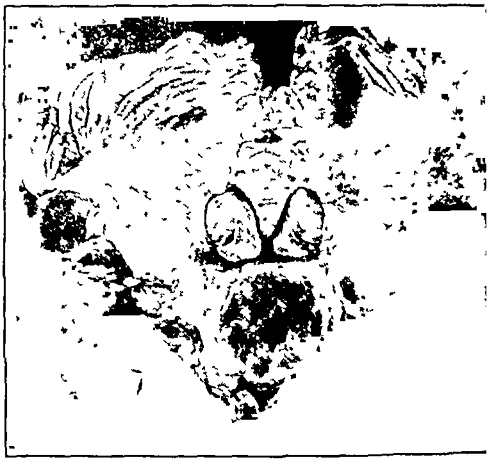
FIG. 13



Solitary tuberculoma of the cerebellum. (Museum, National Hospital.)

On section they present a uniform opaque, appearance, with areas of scattered softening periphery is softer, greyish, and translucent, a surrounding brain is usually softened. They tend to undergo suppuration. Forming t well-defined mass, a tuberculoma may be mistaken for a true tumour. Frequently t more than one present, in which case they may the same or different parts of the brain.

FIG. 14



Metastatic carcinoma of cerebellum, secondary to (Museum, National Hospital.)

Tuberculoma of the brain may occur in the a of other clinically recognisable tuberculous Suspicion as to the true nature of the tumour aroused by the presence of hereditary tenden tuberculosis, a history of exposure to inf favouring its development, a history of sympt a primary focus elsewhere in the body, or the p of local or of general evidence of tube infection.

The problem for the neurological surgeon i difficult one. The surgical outlook for u recovery following extirpation is exceedingl With a few notable exceptions, usually in adu the cases have succumbed to a tuberculous me at varying intervals following removal. The n may arise of giving relief to pressure sym especially when the tuberculoma is situated the tentorium. If so, one should be conte a wide decompression, relying upon constit treatment and heliotherapy to deal with the But the rarity with which a healed tubercul met with post mortem is an index of the r such treatment. Finally, it should always b in mind that other forms of tumour may o tuberculous subjects.

Metastatic Carcinoma

According to Boyd, in from 3 to 5 per cent. c tumours the growth is secondary. But as out by Walshe, the frequency of secondary car in the brain is difficult to estimate, occurring as as a terminal phase in visceral carcinoma, w manifestations are of an indeterminate ch and usually attributed to the effects of the

He thinks, therefore, that its incidence is
ıan that usually given. It is only in those
which early metastasis produces predominant
l symptoms in the central nervous system,
any clinical signs pointing to the presence
ary lesion, that are likely to undergo a full
ical examination. It is in these cases,
r, that the usefulness of an X ray examination,

of the literature that the clinical picture is
plicated and confused that the value of differ-
points in any particular case must be limited.
cords, both clinical and post mortem, of Parker's
lso illustrate the great variability in the course
ndencies of the disease and the difficulties in
sis. Thus it only emphasises the necessity of
plete general physical examination in every
f disease of the central nervous system.

Parasitic Cysts

se comprise the cysticercus cellulosæ and hydatid

ticercus *cellulosæ*.—With a greater stringency
inspection of meat and the gradual disappear-
of the *T... solium*, these cysts have become
ommon th... formerly. When they are found
brain it ...mmonly been in males between
40 and 60 years of age. They usually occur in large numbers scattered on the surface, or in the substance of the brain. They are frequently found swimming free in the ventricles or adhering to the ependyma. They are also found in the arachnoid cisterns at the base of the brain. A single parasite is more uncommon, although out of 72 cases collected by Stern, 53 had a solitary cysticercus of the fourth ventricle. When situated here they may give rise to a marked hydrocephalus by occluding the aqueduct of Sylvius.

The cysticercus in the brain is almost always formed by a capsule which encloses the parasite floating in a clear fluid. Hence they appear when found as a cystic vesicle, either floating free or fixed. Each tumour varies in size from that of a pea to a walnut. The symptoms are protean, and their inconstancy and variability has been explained by the power of movement possessed by the parasite. Convulsions and mental impairment appear to be prominent features of the disease. When occurring in the fourth ventricle it may remain latent until sudden death occurs. On the other hand, it may give rise to occipital headache, vertigo, vomiting, cerebellar ataxia, respiratory and circulatory disturbances, and to glycosuria. The intermittence of these symptoms is very characteristic, the patient being comparatively well between the attacks, and able to carry on his ordinary life. Sudden rotation of the head may bring on vertigo and vomiting, and may cause the patient to fall down. Bruns regards this symptom as pathognomonic of cysticercus in the fourth ventricle.

Except in the presence of cutaneous cysticercus, or definite evidence or possibility of infection, a positive diagnosis is unlikely, unless Brun's symptom can be elicited. Cases, however, are reported in which a diagnosis has been made by lumbar puncture and by puncture of the brain. In cases in which a diagnosis has been made of cysticercus of the fourth ventricle, and where there is no indication that the vesicles are freely mobile, puncture of the fourth ventricle, after the usual suboccipital approach, should be performed.

Hydatid cysts are rare and usually single. They have been found in the cerebellum and in the ventricles. They may run their entire course without giving rise to any symptoms, although, as a rule, symptoms of a tumour are present, and a diagnosis of such a lesion is made. The finding of the hooklets and an excess of sodium chloride in the cerebro-spinal fluid on lumbar puncture may lead to a definite diagnosis of hydatid. A local thinning of the skull, due to erosion of the bone by the echinococcus, may be revealed by X rays.

I am greatly indebted to Dr. J. G. Greenfield for his help and advice regarding the pathological specimens illustrated.

AN AGGLUTINATION REACTION IN VARIOLA

BY C. RUSSELL AMIES, M.D. LOND., D.T.M. & H. ENG.
RESEARCH FELLOW IN BACTERIOLOGY, LISTER INSTITUTE, LONDON

A METHOD of obtaining pure suspensions in saline of the elementary bodies of vaccinia (Paschen bodies) has recently been described by Ledingham (1931). Such suspensions are readily agglutinated by anti-vaccinal sera, and it has been possible with the aid of this new technique to study the development of agglutinins for elementary bodies in animals infected with the virus of vaccinia (Ledingham, 1932).

An obvious extension of this work was the investigation of variola on similar lines, in the expectation that light might thereby be thrown on many still obscure problems concerning the interrelationships of the various pock viruses. The following brief communication contains a record of certain basic data which have been obtained from a study of the development in the sera of variolous patients of agglutinins for the elementary bodies of variola.

SOURCES OF MATERIAL AND TECHNICAL METHODS EMPLOYED

A supply of virulent material (crusts and seropus) from severe cases of small-pox was obtained through the courtesy of Prof. H. W. Acton, of the School of Tropical Medicine and Hygiene, Calcutta. Similar material from mild cases of small-pox (alastrim) was obtained from patients at the Long Reach Hospital, Dartford, through the kind permission of the medical superintendent, Dr. A. F. Cameron.

Variola major.—A 1 in 100 saline suspension of the Calcutta variola scabs was inoculated by scarification of the skin of a *rhesus* monkey. Unfortunately this material proved to be of low virulence, resulting only in the production of a few small papules. These were lightly scraped on the fourth day of infection. The pulp so obtained was insufficient for the preparation of an elementary body suspension and was, therefore, used to infect a rabbit, the pulp being ground up in saline and the supernatant fluid obtained by lightly centrifuging this suspension being injected intradermally into the shaved skin of the back. Four days later each site of inoculation was marked by a red, much elevated papule, 5 to 7 mm. in diameter, with a yellow necrotic centre. The animal was then killed and the papules were excised with aseptic precautions. The tissue removed was cut up very finely with scissors and ground thoroughly in a mortar with distilled water. The resulting suspension was placed in a separating funnel with an equal volume of ether in order to extract all the fatty materials, the mixture being shaken at frequent intervals. At the end of 24 hours the lower aqueous layer was drawn off and then centrifuged for two hours at an approximate speed of 6000 revolutions per minute. The sediment so obtained was resuspended in distilled water and again subjected to rapid centrifugation for two hours. Finally the sediment was suspended in 0·25 per cent. formalin in normal saline, and centrifuged at a relatively low speed until all debris had been precipitated. Smear preparations of the supernatant fluid showed large numbers of elementary bodies with practically no other formed elements.

Variola minor.—The English variola material, being fresh, produced a more satisfactory reaction when inoculated upon the skin of a monkey, and the amount of pulp obtained was sufficient for the preparation of an elementary body suspension directly from the monkey tissue. Owing, however, to the hæmorrhagic nature of the lesions it was found necessary to repeat the process of rapid centrifugation four times before a pure suspension could be obtained. A rabbit was also inoculated intradermally with a suspension of the same monkey pulp. The reaction produced was not so marked as that obtained with the Calcutta strain of virus, but a satisfactory suspension was eventually obtained from material excised on the fourth day of infection.

Preliminary tests showed that these three elementary body suspensions, one obtained from the

Indian strain of virus, and two from the English strain, were agglutinated in characteristic fashion by a known anti-variola monkey serum. Owing possibly to its larger content of elementary bodies, clumping was more definite in the suspension obtained from the Indian strain and the agglutination titre was slightly higher than that given by the other suspensions. A microscopic agglutination technique was used in all the tests, the results being read under a two-third inch objective after incubation at room temperature (average 65° F.) for 24 and 48 hours.

AGGLUTININ PRODUCTION IN MAN

The agglutination test as above described was carried out on sera from ten cases of severe small-pox in Calcutta and on 28 sera from patients at the Long Research Hospital, Dartford, who were suffering from the mild type of small-pox (variola minor or alastrim) prevalent in England. The results are given in Tables I. and II.

N.t. = not tested.

In the case of the Calcutta sera it must be noted that the specimens were necessarily over a month old before they could be tested. It is probable that a larger number of these would have given positive results had they been fresh. The sera from the Dartford cases were stored in the cold room soon after collection and were tested not later than three days afterwards.

From the results shown in Tables I. and II. it appears that the development of immunity to the virus of variola, both in its classical form and in the mild form prevalent in England, is accompanied by the production of agglutinins which are specific for the variola elementary body. Suspensions of the elementary bodies of vaccinia are not agglutinated by the small-pox antisera. The agglutinins for variola elementary bodies do not reach high titres, but it is possible that further refinements in technique may yield suspensions of higher agglutinability.

A further fact of considerable interest was disclosed by the results of tests carried out on the blood of a few individuals who were exposed to infection with variola, but who were immune to it by reason of previous vaccination. Samples of blood were taken from a medical officer and a nursing sister at the Long Reach Hospital and from a laboratory attendant at the Lister Institute, who was responsible for feeding the variolated monkeys used in this investigation. All three had been vaccinated several times. Agglutinins for both variola and vaccinia were found in the serum obtained from the sister and from the laboratory attendant, but none were found in the blood of the medical officer.

Some months before commencing to work with variola virus I was revaccinated and samples of my blood were taken at regular intervals in order to study the agglutinin response. No agglutinins for vaccinia were present previous to vaccination. The agglutinin-titre for the Paschen body suspension rapidly rose, reaching a maximum of 1 in 160 on the seventh day of infection. Thereafter the titre slowly fell, reaching 1 in 4 on the 52nd day after vaccination. Later I was exposed to infection both from handling the variolated monkeys and from the small-pox patients isolated at Dartford. Three weeks after *commencing the work on variola my blood gave a* positive agglutination response with the variola suspension to a titre of 1 in 64 and with the vaccinia suspension to a titre of 1 in 128.

AGGLUTININ PRODUCTION IN ANIMALS

The inoculation of either the Indian or the English strain of variola virus into monkeys resulted in the production of agglutinins for the variola elementary body but not for the vaccinia elementary body. Rabbits infected with pulp obtained from these monkeys produced, however, agglutinins for both variola and vaccinia. A more detailed description of these experiments will be withheld until the results of further work with hyperimmune sera are available.

DISCUSSION

The experiments described, though by no means exhaustive, demonstrate that agglutinins specific for the elementary body of variola are produced in response to infection of man or monkey with this virus.

The fact that vaccinia elementary bodies are not agglutinated by the sera of variolous patients furnishes a striking difference between the agglutination test and the vaccinia-variola flocculation reaction so carefully studied by Craigie and Tulloch (1931). In the latter reaction, it will be remembered, a serum from a rabbit hyperimmunised with vaccinia virus is brought in contact with an antigen which consists of a saline extract of variola crusts. Craigie (1932) has recently shown that the flocculable substance in this antigen will pass through a Seitz E.K. filter which is capable of holding back the elementary body, thus proving conclusively that the flocculation test is essentially a precipitin reaction. It would seem likely, therefore, that vaccinia and variola share some common antigen, although separate agglutinins are produced in the body in response to these two viruses.

Further work now in progress is designed to throw light on these serological affinities and their bearing on problems of active immunity among the pock viruses.

SUMMARY

1. A method is described for obtaining a pure suspension in saline of the elementary bodies of variola.

2. Variola elementary body suspensions are agglutinated by the serum of patients convalescent from either the mild or severe type of small-pox, but vaccinia elementary bodies are not agglutinated even in the highest concentrations of such sera.

SOME FACTORS TO BE TAKEN INTO ACCOUNT IN THE TREATMENT OF HYPERTONY

By I. Harris, M.D. Königsberg
HON. PHYSICIAN TO THE LIVERPOOL HEART HOSPITAL

Recently C. L. G. Pratt and I have shown [1] that the administration of certain drugs for the purpose of reducing pressure in cases of hypertony results in a disturbance of the equilibrium of the different blood constituents. Patients with hypertony whose pressure was reduced artificially showed an increase of blood-urea and non-protein nitrogen; the water-excretion function was depressed, the alkali reserve of the blood diminished, and the cardiac reserve power lessened. These facts suggest that the indiscriminate use of pressure-reducing drugs is extremely undesirable. In this paper an attempt is made to study certain methods of treatment of hypertony in relation to their action on blood chemistry.

At the outset it is necessary to differentiate between methods of treating hypertony whose object is simply the reduction of pressure without regard to ætiological factors, and methods whose aim is to reduce pressure by treating the causal factor. The first must be of doubtful value, the second can do nothing but good.

The patients were kept in bed. During the first week no treatment was given. During the second week Collosol sulphur was injected, 3 c.cm. daily. During the third week six pints of water were given daily. The patients were kept on a standard diet all the time. In other cases the procedure was altered. In the first week the patient had no treatment; in the second week he was put on salt- and sugar-free diet; in the third week a diet consisting mainly of carbohydrate, and in the fourth week a pure meat diet was given.

WATER

I know of no method of reducing blood pressure which is uniformly efficacious in all cases. Indeed, considering the various ætiological factors of hypertony, no uniformity can be expected. The drinking of large quantities of water effects a striking reduction in the blood pressure in many cases. G. McLoughlin and I [2] used this method with good effect in cases of high blood pressure with a high degree of viscosity for the purpose of lowering the latter. At that particular time it was not clear to us why the action of water should have been what it was. I am now in a better position, I believe, to conjecture the reason of its beneficial action. Table I. shows that in cases under sulphur treatment, pari passu with the reduction of pressure, there was an accumulation of deleterious substances in the blood. The same phenomenon was observed when the pressure fell simply as the result of heart failure. This suggests that high pressure in cases of hypertony is needed for the purpose of maintaining a normal chemistry balance in the blood. On the other hand, cases under treatment with water, although the blood pressure was definitely reduced, showed a normal blood chemistry. The beneficial effect of large doses of water is probably due to the fact that it enables the kidney to excrete urea and allied substances more easily. In this way a normal blood chemistry balance is maintained and there is no longer a necessity for a compensatory hypertony.

Chlorides.—Nil. * Mg. per 100 c.cm. B.P.=Blood pressure.

It has been contended that large quantities of water increase the strain on the heart by increasing the blood volume. It is, however, obvious that a treatment which reduces pressure and blood viscosity must also diminish the cardiac strain. Moreover, R. Mennie and I, in a yet unpublished work, have showed that there is no hydræmia after the imbibition of large quantities of fluid. Therefore there cannot be an increased blood volume under this treatment. So far as the kidney is concerned, the drinking of large quantities of fluid is all to the good. It has long been established that the work which the kidney performs in passing concentrated urine is far greater than when the urinary output is diluted.

SALT- AND SUGAR-FREE AND PROTEIN DIET

It is clear from Table II. that a salt- and sugar-free diet reduces and a protein diet increases the blood pressure. Broadly it may be stated that in hypertony the blood pressure stands in an inverse ratio to the non-protein nitrogen level in blood. It is true, as we have seen, that after the imbibition of large quantities of water both the pressure and the non-protein nitrogen (N.P.N.) tend to be lower, but in this instance the action of the water is what it is because it apparently does away with a causal factor of hypertony (viz., increased blood viscosity). The blood-urea is somewhat increased under the salt- and sugar-free diet and somewhat diminished under meat diet, although urea is an end-product of protein. It is possible that a low blood-urea after meat may be explained by the diuretic properties of this substance. The increase of blood-urea after a salt-free diet is by no means so pronounced and constant as it is under conditions where pressure-reducing drugs are given.

---

[1] The Lancet, 1931, ii., 629.
[2] Quart. Jour. Med., 1930, xxiii.

It is possible the increase has something to do with the maintenance of the normal osmotic pressure, which is lowered by a salt-free diet.

* Mg. per 100 c.cm.

After venesection there was a pronounced reduction of blood pressure, and the blood biochemistry remained normal, but, as has been the experience of many others, the beneficial effect of this procedure is only transitory. Within less than a week the blood pressure reached its usual level.

Table III. is interesting because it shows that the urea-concentration test so much in vogue is not always quite reliable. Urea was given to a patient before the blood pressure was raised and also when the pressure was relatively low and the blood-urea high. The effect of the same quantity of urea was different in the same patient under these two conditions. Apparently, when the blood-urea is already high, an additional dose of urea may exert a pronounced diuretic effect which may result in a lowering of the blood-urea level. This was the reason why the urea-concentration test has given no consistent results in this investigation.

TABLE III.—*Blood-urea*
Mg. per 100 c.cm.

Case.	Before blood pressure was reduced.		After blood pressure was reduced.	
	Administration of urea.		Administration of urea.

2 ..	85	102	102	78
3 ..	34	65	41	44
4 ..	60	128	63	105

The conclusion is that it is undesirable to employ drugs for the purpose of reducing pressure. On the other hand, the imbibition of large quantities of water ought to be encouraged. The diet should be of low protein content, and excessive amounts of salt should be avoided.

I should like to acknowledge my indebtedness in regard to this work to Mr. G. Williamson.

FURTHER STUDIES ON THE ANTERIOR PITUITARY-LIKE HORMONE

WITH SPECIAL REFERENCE TO IRREGULAR UTERINE BLEEDING *

BY A. D. CAMPBELL, M.D., F.R.C.S. CANADA, M.C.O.G., F.A.C.S.

(From the Department of Obstetrics and Gynæcology, McGill University, Montreal)

A PRELIMINARY report on the treatment of irregular uterine hæmorrhage by hypodermic injection of the anterior pituitary-like hormone extracted from human placentæ was read before the Winnipeg meeting of the British Medical Association in August, 1930 (Campbell and Collip, 1930). The results were so promising that a series of 84 cases has been more continuously and completely studied.

The alleged association of certain physical characteristics with endocrine disorders was a matter of special interest in this study. In each case, therefore, a detailed general history, as also an exhaustive menstrual history was always obtained as a preliminary, while the complete physical examination had special reference to possible endocrine relations. It is interesting to note that in the 60 per cent. of our cases which were examined by X rays to ascertain any possible gross abnormality in the conformation of the sella turcica, no bony changes were found.

Determination of blood pressure, blood Wassermann reaction, and urinalysis were carried out as a routine. The basal metabolic rate in all instances was found to lie within normal limits. Particular emphasis was, of course, laid on the pelvic examination to determine the position, shape, and size of the uterus, and the state of the adnexa; all cases with endocervicitis or birth trauma which in themselves would lead to such pelvic congestion as to predispose to, or cause menorrhagia or metrorrhagia, were excluded. Post-menopausal metrorrhagia was also omitted from the study, on account of its frequent association with carcinoma of the fundus or malignant changes in the adnexa. Nor should one leave out of consideration the possible existence of small myomata in the fundus, for, as Beckwith Whitehouse has pointed out, small mural fibroids may so interfere with the contraction of the uterus as to cause excessive menstrual flow. Moreover, since the surfaces of the endometrium are normally in constant apposition, the presence of any submucosal myoma or other irregularity in the surface, allows of and predisposes to local hypertrophy or polyp formation; myometrial changes in persistent uterine bleeding have been described by Schroeder, Whitehouse, Young, and Lockyer. Too much stress cannot be laid on the need of careful exploration of the cavity of the uterus in order to determine the character of the surface of the wall, as well as to obtain samples of endometrium for histological study.

TYPES OF HÆMORRHAGE

In an earlier communication I stated that cases of excessive uterine bleeding may be grouped into several categories according to their menstrual history. (Table I. and Fig. 1.)

The last group (G) may be further subdivided into four categories, according to the mode of development of the continued bleeding which may arise.

---

* Read before the Section of Physiology and Biochemistry of the British Medical Association on July 28th.

(*a*) By confluence of regular cycles of varying length of interval with unduly prolonged duration of the flow.

(*b*) By confluence of irregular periods of metrostaxis.

(*c*) Spontaneously, either after a normal menstrual cycle or more commonly after a period of amenorrhœa.

(*d*) As an outcome of puberty.

TABLE I.—*Varieties of Abnormal Uterine Hæmorrhage*

—	Length of cycle.	Amplitude of flow.	Duration of flow.
A	Normal.	Excessive.	Normal.
B	,,	,,	Prolonged.
C	,,	,,	Normal, superimposed on constant bleeding background.
D	Short (19–24).	Normal or excessive.	Normal or prolonged.
E	,, (14 days).	,,	Irregular.
F	A cyclic intermittent bleeding.	Irregular.	,,
G	Continuous excessive hæmorrhages.		

Excessive bleeding may appear at any time from the menarche to the menopause. In cases of metrorrhagia, the size of the uterus may be within normal limits, but more frequently it is symmetrically enlarged, and its consistency may wrongly suggest subinvolution or a sessile fibromyoma. When bleeding commences at puberty the uterus is not necessarily enlarged, but its shape becomes similar to that of the parous woman's uterus, in that the corpora-cervical angle is less acute. Even in young patients suffering from excessive uterine bleeding it is found that the cervix is slightly patent and easily admits a small sound. In the parous woman the patency is more pronounced.

I should like to emphasise here that the endometrium in menorrhagia and metrorrhagia gives little information regarding the character and severity of uterine bleeding; nevertheless, it is to some extent true that the changes produced in the mucous membrane may be taken as an index of ovarian function in cases otherwise apparently normal. It is clear that where cycles exist samples of the endometrium must be obtained at the same part of the epoch in parallel cases if any comparison is to be made. If the cycles are masked by continuous hæmorrhage, the interpretation becomes more difficult. Moreover, Evans has pointed out, in a critical review of the work of Schroeder, that premenstrual changes in the endometrium occur in some cases immediately after the cessation of the period, and that exactly similar changes may occur very late in the interval, so that the value of comparisons of one case with another, even if samples were obtained at the same time in relation to the apparent menstrual cycle, appears to be hazardous.

It has been shown by Schroeder and by W. Shaw that in cases of metropathia hæmorrhagica the ovaries contain no fresh corpora lutea, but a follicle with cystic changes is the rule (Fig. 2). Although Novak has not confirmed this finding, it is generally considered that the endometrial change is associated with subnormal ovarian function. However, the complete removal of the ovaries does not lead to any similar condition, and J. B. Collip (1932) has found that the fluid from such follicular cysts in cases of this type of irregular uterine bleeding may contain up to 25 rat units of œstrin per c.cm. This suggests that there is a secretion of œstrin from the ovaries which is disproportionately great, whether absolutely or relatively to the reduced activity of luteal tissue which may be inferred from the appearance of the ovaries. With regard to the suggestion made by Shaw, that the ovary produces some abnormal toxic substance, it may be stated that similar suggestions have been made from time to time for other organs of internal secretion, but in every case the view that disturbances are due to excessive or deficient formation of the normal hormone has prevailed.

EFFECT OF THE HORMONE ON BLEEDING

Animal experiments show that excessive doses of œstrin not only affect the production of monophasic cycles, but in continued administration may eliminate the cycles. Excess œstrin affects the entire human organism. As regards the uterus the effect is not limited to the endometrium, but affects the myometrium as well, and herein lies an important consideration. The continued administration of moderate doses of the anterior pituitary-like hormone (A.P.L.) in immature female rats leads to the precocious appearance of normal œstral cycles (Collip, Thomson, McPhail, and Williamson), while the ovaries rapidly attain the size and appearance of those of normal adults. There is, therefore, reason to suppose that this substance might directly, or through the anterior pituitary, correct the changes observed in the ovaries in metropathia hæmorrhagica, and lead to the appearance of normal balanced ovarian function and the recovery of normal uterine structure and function. This expectation was realised in many cases of varied types.

Legend.—(L) Of these, bleeding dated from puberty in five cases. (M) This case recently curetted, non-response probably due to endometritis (infected). (N) Small submucous fibroids ½ to 1 cm. in diameter. (H) Aged 51. Uterus explored and found normal. Endometrium showed moderate cystic hyperplasia with œdema of the stroma. (P) Two returned to 14-day cycles. (Q) One of these, condition dates from puberty. (R) Entire group of recent origin. (S) Existing since puberty. (T) One chronic nephritis, one due to pelvic inflammatory disease, two showed after hysterectomy, uterine musculature hyperplastic and in places atrophied, ovaries large, follicular cysts with no potential Graafian follicles, no evidence of recent corpora lutea. One case unexplained.

Preparations of different strengths were used, but the dosage was so adjusted that the patient received at least 40 day-rat units per injection. Our best results were obtained by an injection every day for seven days, then every second day until the patient had passed through two menstrual cycles. When the menstrual flow became of normal duration and proportion treatment was discontinued. A high percentage of cases in all groups responded as shown in Table II. In all groups there were some instances of recurrences of menorrhagia or metrorrhagia, but upon reinstitution of the therapy the cases responded with comparatively few injections. Group D, however, proved disappointingly refractory.

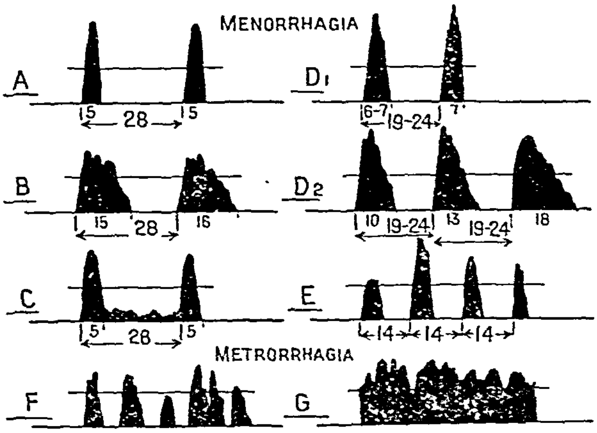
In typical cases of so-called metropathia hæmorrhagica, such as those shown in Fig. 3 appended, the institution of A.P.L. treatment did not cause any immediate cessation of bleeding; indeed, while hæmorrhage commonly became less copious, there was no striking change for eight to ten days, and then the bleeding became very profuse, usually worse in the morning, with sharp "spurts" throughout the day. This exacerbation, however, gradually subsided, and the bleeding practically disappeared except for slight metrostaxis, for from four to five days' duration, or lasting into the next cycle. The majority of cases, when treatment was continued, manifested a menstrual period on the twenty-eighth day after the first exacerbation (which is regarded as an epoch superimposed on the background of more or less continuous hæmorrhage), and at this period the hæmorrhage was usually greater than a normal flow in duration and amount, clots and large mucosal fragments were passed, accompanied by considerable pain. Usually the treatment was discontinued at this point; if, however, the uterus remained large, and no pain was experienced, the treatment was continued; it was assumed with some reason that the bleeding of metropathia, which is characteristically painless, was not overcome and that the myometrium had not returned to normal

(Fig. 4, Case A). It may be that several menstrual cycles must elapse before the endometrial overgrowths are completely shed, since Whitehouse has shown that the uterine mucosa is not completely nor uniformly shed, even in normal menstruation. On the other hand, in cases which were curetted prior to the institution of therapy the result was considerably hastened (Fig. 4, Case B). Once cycles of normal interval and proportion were established, they continued normally thenceforward, and in all cases which responded the uterus too returned to normal proportions. This maintenance of normal rhythm has been followed in some cases for over two years. There were, of course, exceptions to this typical history—for example, in women near the menopause, where the cessation of hæmorrhage is followed by amenorrhœa. It is of interest to note that the vasomotor disturbances of the menopausal syndrome did not appear in such cases.

In patients with continuous uterine bleeding dating from puberty the gross response was satisfactory, no matter how long the hæmorrhage had continued, though after one or two cycles the normal rhythm was not perfectly established, being punctuated with periods of amenorrhœa lasting up to three months. Only very occasionally did the symptoms recur. It is worth noting that over 10 per cent. of the cases in this entire series had at some time or another previously been treated with radium or X rays, with only temporary improvement.

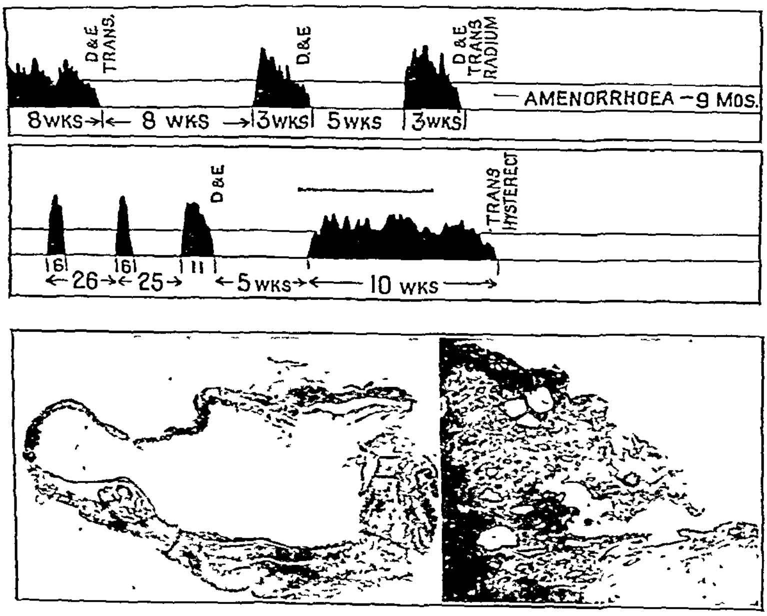
In cases of post-partum metrostaxis the results were particularly good; there were ten cases treated, and all responded.

FIG. 1



This represents the eight different menstrual types into which the cases have been arbitrarily divided. D1 and D2, however, may be found at different times in the same individual. The graph indicates the quantity and duration of the bleeding. The upper horizontal line represents the normal blood loss, whilst the length of the interval in days is shown by the figures below.

FIG. 2



Aged 35, married, 3-para. Some 20 months are represented graphically on the chart. Left ovarian cyst size of hen's egg. Uterus slightly enlarged. The endometrium absent in the lower portion of the uterus. On section, the uterine musculature showed definite hyperplastic changes. In the fundus the endometrium slightly polypoid, and microscopically showed cystic hyperplasia. On serial section, left ovary atrophied and cystic; right ovary contained corpora lutea, but not of recent development. No maturing Graafian follicles to be found. The greater portion of the ovary replaced by scar tissue, showing almost complete replacement of ovarian tissue by cyst (left ×¾) also corpus luteum not of recent development. Section of endometrium (right ×5) shows cystic hyperplasia.

Excessive menstruation following abortion responded similarly.

When pelvic inflammatory disease was the cause of metrorrhagia or menorrhagia the symptoms were aggravated by this method of treatment.

In cases of polymenorrhœa with flow of normal character, but recurring at irregular short intervals, it was sometimes possible to increase these intervals by three or four days; the previous condition, however, recurred when treatment was discontinued.

OTHER USES OF THE HORMONE

May I again emphasise the need of an outlook *that extends beyond the* endometrium and the study of mere local changes? The entire human organism is influenced by ovarian function. While the endometrium is a tissue easily accessible to study, the pattern of which alters from day to day, there are changes of a general biological character which may give rise to clinical symptoms, though they are not evident in the endometrial architecture.

In this connexion clinical trial of A.P.L. extract was extended to other conditions. Thirty cases were treated for menopausal symptoms and 24 responded. The improvement was marked even when a considerable time had elapsed since the last menstruation. In six of these cases in which periods had ceased for various lengths of time up to one year, menstruation reappeared in from eight to ten days.

In cases with mastalgia, or so-called chronic mastitis, particularly those associated with abnormal menstrual cycles, not only was the pain relieved, but the small pea-like nodules in the breast disappeared. Let me add here that the normal mammary gland was never affected even in prolonged administration of A.P.L., nor was the post-partum breast in any way altered.

FIG. 4

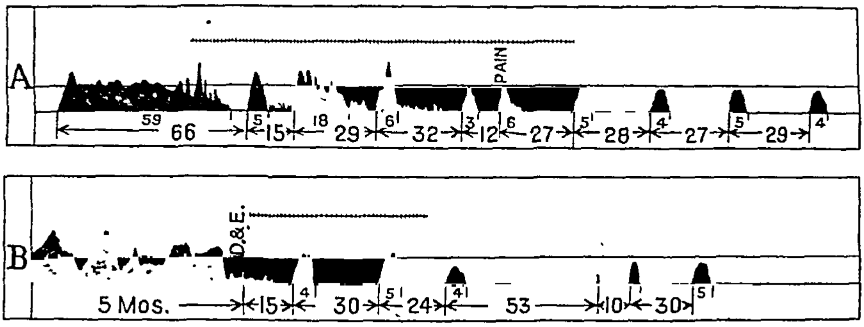


Chart showing history of two cases treated with A.P.L. The horizontal cross-hatched line indicates the period through which treatment was administered. A, was curetted four years before the institution of therapy. *Curettings at that time showed a hyperplastic endometrium.* B, was mildly curetted immediately before the institution of therapy. Microscopical examination showed cystic hyperplasia of the endometrium with some œdema of the stroma. (Fig. 3 c.)

A form of urticaria associated with subnormal ovarian function and refractory to all other forms of medication disappeared with the administration of this hormone. Vomiting of early pregnancy was not improved, though it is worthy of note that in none of the cases treated was there any tendency to

FIGS. 3 A B C

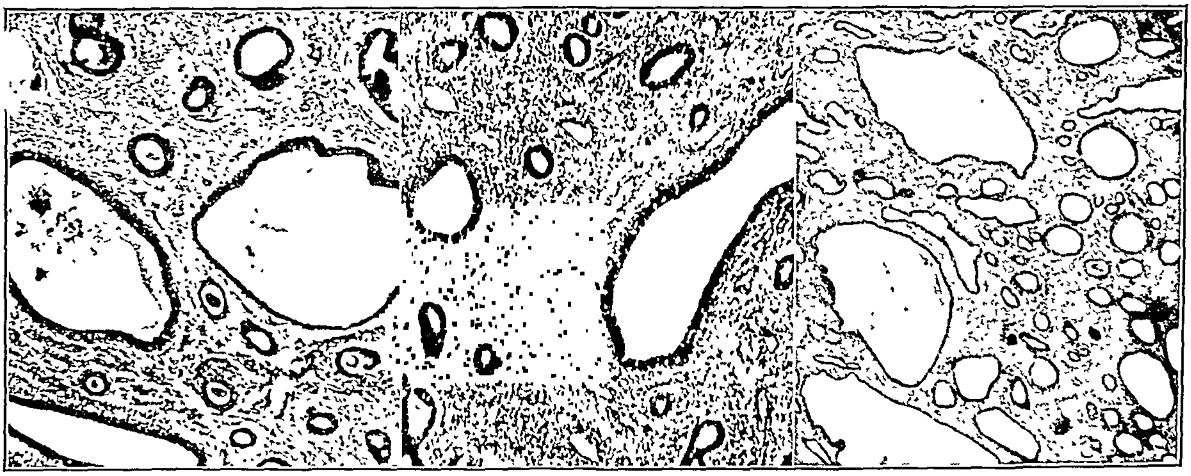

FIG. 3 A.—Aged 21, single, puberty irregular. Metrorrhagia lasting for several months. During the past seven years was curetted three Bleeding profusely for four months prior to coming under observation. Uterus slightly enlarged, very lepth. Contour of cavity normal but hard. Photomicrograph (×40) shows marked glandular and cystic hyperplasia. A.P.L. administered for six weeks. Normal cycles followed after an initial lapse of menstruation for three months.

B.—Aged 35, 2-para. Menstrual history characteristically normal until three years ago, when periods became more profuse. For two months, metrorrhagia in addition to menorrhagia. Section (×40) shows polypoid hyperplasia with cystic glands. Stroma œdematous. After two months' treatment menstruated normally and cyclicly. One year later symptoms recurred, but with six injections of A.P.L. intermenstrual bleeding ceased and cycles became of normal proportions.

C.—Aged 43, 4-para. Menstrual history characteristically normal. Metrorrhagia for past six months. Uterus enlarged, firm, but normal in shape. Parametrium and adnexa apparently normal. Cervix slightly patent, depth of cavity 4½ in. Walls firm, contours normal. Gently curetted. Endometrical stroma (×20) shows irregular areas of œdema. Hæmorrhagic areas throughout; glands greatly dilated, containing blood and hyaline secretion; epithelium of columnar type; many cells vacuolated. No areas of infiltration. Treated for two months. Subsequent history represented in Fig. 4 B. Uterus returned to normal proportions.

abortion. Cases of sterility, in most instances associated with polymenorrhœa, did not become pregnant, though two cases suffering from metrorrhagia became pregnant while being treated, and one other with a similar condition became pregnant immediately after cycles were established.

Dysmenorrhœa was intensified. It has previously been pointed out that in the treatment of menorrhagia and metrorrhagia the appearance of pain frequently marked the beginning of improvement. Intermenstrual pain (Mittelschmerz) became more severe under treatment.

In cases with normal cycles no change either in the amount of hæmorrhage or the duration of the interval was observed, even when the injections were continued for months.

A typical menstrual period occurred in ten cases of secondary amenorrhœa in from 10 to 14 days after therapy was instituted. No success was obtained in similarly treating primary amenorrhœa. The preparation of anterior pituitary-like hormone used by us did not cause any local symptoms or alteration in blood pressure levels or give rise to systemic reaction.

It is generally held that the corpus luteum is essential for normal menstrual cycles, but I believe that this dogma must be modified, as pointed out in a previous communication (Campbell and Collip, 1930). Moreover, Corner and Hartman have shown that the corpora lutea are not necessarily present in ovaries showing cyclic activity as manifested by menstruation. Ovarian function in the human may, therefore, be largely appraised by the regularity, amplitude, and duration of the menstrual epochs as well as by general well-being.

IMPRESSIONS

(1) There are several types of irregular uterine bleeding which may be distinguished by their menstrual histories. In selecting cases for treatment, correct diagnosis is essential; the organs in the pelvis must be palpably normal, and the presence of neoplasms of the uterus must be excluded. (2) Menorrhagia and metrorrhagia due to inflammatory diseases are aggravated. (3) Metropathia hæmorrhagica responds particularly well. Pain is taken to signify that the musculature has returned to normal tone, and that the hyperplastic endometrium is being rapidly expelled. (4) Response is not so consistent in metrorrhagia of puberty, and treatment is followed by periods of amenorrhœa. (5) Menopausal symptoms are alleviated. (6) Mastalgia, if accompanied by disturbed menstrual cycles, frequently subsides. (7) No permanent improvement is noted in simple polymenorrhœa. The symptoms of dysmenorrhœa are intensified. (8) There is no effect in pregnancy, and no effect upon normal menstrual cycles as regards interval, amplitude, or duration; no local or constitutional symptoms are observed. (9) It is considered that the effect of the anterior pituitary-like hormone is to cause the ovary to resume a complete and balanced endocrine activity, in place of one that is unbalanced and incomplete.

The extract used in these studies was prepared in the Bio-Chemical Laboratory of McGill University by Prof. J. B. Collip. The method of preparation and physiological properties of the anterior pituitary-like hormone have been published previously (ref. 3).

I wish to thank the staffs of the Royal Victoria Hospital and the Montreal General Hospital for their kind coöperation.

CLINICAL OBSERVATIONS ON MALARIA TREATED WITH TEBETREN

BY D. G. STOUTE, M.B. EDIN.
DISTRICT SURGEON, MTUNZINI, ZULULAND

AN account by Dr. R. Green in THE LANCET of April 16th (p. 826) of the successful treatment of malaria with Atebrin, a new synthetic drug consisting of an acridine compound, has stimulated me to write my clinical observations on the treatment of malaria with a new preparation, known as Tebetren, which combines the virtues of quinine and an acridine dye, and does not discolour the patients during treatment. Its composition is methyl-hydrocupreine-methyl-acridine-dehydrocholate, and it is unnecessary to add any other preparation as the quinine is combined with the dye. To render the preparation non-toxic the compound is united with a bile-salt. Tebetren was supplied to me for trial by the Natal Health Department in 1930 in tablets of about grs. 3 each, pale yellow in colour and with a bitter taste. When crushed the tablet is slightly soluble in cold water, more so in alcohol, and insoluble in ether. The colour of the solution in water and alcohol is greenish-yellow.

At my suggestion the manufacturers supplied me with the preparation in ampoule form (2·1 c.cm. in each). Intradermally the preparation is painful and causes sloughing of the skin at the site of the injection, with inflammatory reaction around. Sloughing is not however deep-seated. Intramuscularly into the gluteus maximus little or no pain was complained of, nor was there any local reaction at the site of injection. Routine was oral treatment; in cerebral cases one ampoule was injected intramuscularly every four hours during the day until the patient was conscious, and then oral administration continued. I have not administered the preparation subcutaneously or intravenously, although it is claimed that subcutaneous injection with massage will not cause any local reaction. It is claimed to act more readily on schizonts than gametes. It stimulates the phagocytic power of the blood for a much longer period than quinine and exerts a destructive effect on any stage of development of the malarial parasite.

To date some 80 European adults and about 20 children whose ages varied from 2 to 12 years have been treated: the course for adults being 2 tablets every 4 hours, if possible including the night, for 30 uninterrupted doses, for children ¼ to 1 tablet according to age every 4 hours for 30 doses. Four courses (120 doses) are given and as tebetren is cumulative in action a rest of 3–5 days is necessary between each.

European patients (14 in number) so treated who gauzed their living quarters to safeguard themselves from reinfection have not relapsed for a period of over 18 months. Infections that were resistant to quinine treatment reacted to tebetren and gave three negative monthly smears after the fourth course.

The original test cases in 1930 were an indiscriminate selection of an Asiatic (Indian) and 14 natives (Basuto, Xosas, Zulus), all proved by slides to be suffering from subtertian and benign tertian malaria. Unfortunately these cases being of the mobile population were discharged from hospital after a negative phase had been established by uninterrupted 4-hourly dosage. One Zulu however was kept under observation for a period of six months. In his case, a negative phase having been established, I was unable to precipitate an attack of malaria by adrenaline or douching with cold water after severe work.

Patients complained of what I interpret to be mild toxic effects—viz., (1) a feeling that the skull was too small for the brain; (2) a lightness of head with or without slight deafness; (3) a singing in the ears. These complaints were made during the first course and got less and less in subsequent courses. Others complained of feeling bad, but could not definitely explain. This type of complaint was met by a large drink of tea or water at the time of dosage, or by alkalising the patient with copious drinks of bicarbonate of soda in water. I quote this last simply as a possible toxic effect, for in many cases it was, I believe, due to malaria.

In the 4-hourly slide controlled cases the results were as follows: In benign tertian infection the average minimum time taken for parasites to disappear from the peripheral blood was 48 hours, in subtertian infection 36 hours. With quinine bihydrochloride grs. 30 per diem the time was: 110 hours for benign tertian, 72 hours for subtertian. I have not treated a case of quartan infection which is a rarity in this area. In neither benign nor subtertian infections have sexual forms of parasites been found. The febrile condition was on the average controlled in both types of infection in 48 hours.

Symptoms of malaria—viz., large spleen, with or without tenderness, aching body, vomiting, headache, &c.—responded readily to treatment, especially the distressing vomiting. Pregnancies varying from five months onwards were uninfluenced by the treatment. One case of cerebral malaria in a native female about six months pregnant was treated energetically with intramuscular injections of tebetren, four hourly during the day, and regained consciousness after a period of four days and nights, when oral administration was continued. She gave a negative slide after the fourth course, and is at the moment going on well with pregnancy uninterrupted.

CONCLUSIONS

1. As compared with quinine the action of tebetren is more rapid.
2. It possesses a lethal action on benign and subtertian parasites and may inhibit the formation of gametes.
3. Patients were more rapidly in a state of recuperative well-being than with other forms of treatment I have used.
4. Little or no toxic effects occurred other than those stated above, and patients (Europeans) who relapsed after three negative tests, and who may have been reinfected at home, readily presented themselves for further treatment.
5. Satisfactory results were obtained in cases resistant to quinine.

I am indebted to Dr. Park Ross, assistant medical officer of health for the Union of Natal, for supplying me with samples of the preparation, and to Dr. B. Sampson, Government pathologist, for examining a number of blood slides.

CHOLECYSTOGRAPHY *

By James F. Brailsford, M.D. Birm.
HONORARY ASSISTANT RADIOLOGIST TO THE QUEEN'S HOSPITAL, BIRMINGHAM

No branch of radiology requires more careful attention to technique and interpretation than that of the examination of the gall-bladder, and the accuracy of the radiologist's reports varies directly with his appreciation and care of detail. The best results will be obtained when he personally carries through the whole procedure. His report is the radiographic evidence on which the clinician should rely, and it should be so worded as to convey an opinion as to the nature of the pathological lesion revealed. A mere description of the appearances presupposes that the clinician can interpret the significance of shadows which he would probably not notice unless the radiologist pointed them out to him. The significance of radiographic appearances is best appreciated by those who make it their sole study; the subject is too vast to permit of excellence in any other specialist subject. Even the regional specialist who attempts to interpret radiograms is usually ignorant of the fundamental radiographic technique and the changes that may be due to alteration of that technique; he may also fail to recognise the appearances familiar to the radiologist in other parts of the body, the knowledge of which may be all-important in diagnosis.

I believe it to be the duty of all radiologists to issue a report with every radiogram sent to the clinician, and it is on the value of his reports that his reputation should be built up. Wise clinicians realise this, and must be familiar with many instances of error due to the folly of inexperienced interpretation.

PREPARATION OF THE PATIENT

The gall-bladder is in close relation to the hepatic flexure and the first part of the transverse colon, the stomach and duodenum, and its shadow may be obscured by opaque or gaseous contents of these organs. If bismuth or any other opaque material has been taken by the patient, a mild aperient should be given two days before the X ray examination, and the patient kept on a light diet during this period. Drastic purgation is likely to result in distention of the bowel by gas which will obscure the gall-bladder shadows. If the patient is constipated a simple enema may be given, followed by a saline enema to wash out the contents of the bowel, taking care that no air is introduced.

PRELIMINARY RADIOGRAPHY

It is essential that before any opaque material is introduced into any organ for radiographic purposes

---

* Based on a paper read before the Section of Radiology of the Royal Society of Medicine.

a preliminary radiogram be taken and carefully studied for any trace of abnormality. Failure to do so may result in faulty diagnosis and the missing of the essential lesion, owing to the obscurity produced by the opaque medium used. In a previous paper[1] I have given a list of the lesions I had discovered by preliminary radiographic examination, and often these were the only pathological signs discovered, and in many cases the cause of the symptoms. On the one hand, the clinical signs and symptoms of gall-bladder disease may be present when this organ is functioning normally, while, on the other hand, gall-bladder disease may be accompanied by signs and symptoms which do not suggest that there is anything wrong with it. In some cases of obscure abdominal disease the inclusion of a preliminary radiogram of the bones of the pelvis may throw light on the pathology of the condition.

The preliminary radiogram of the gall-bladder area I take with the patient lying prone on the Potter-Bucky diaphragm, with the arms folded above the head and the head resting on the left arm, looking towards the right, so that there is a slight rotation of the body to the right. The X ray tube is centred 30 inches above the Potter-Bucky diaphragm, over a point 2 inches to the right of the spine over the last rib, and an exposure of ½–2 seconds, varying with the thickness of the patient, using 100 m.a. (milliamperes) of current. The slight obliquity of the patient will throw the shadows of the gall-bladder away from those of the spine. Well-defined gall-stone shadows and a good shadow of a dye-filled gall-bladder may be entirely missed, because they are superimposed on the shadows of the spinal column. It is obvious, therefore, that if thin gall-stone shadows are to be seen these must be projected away from the shadows of the spine.

The shadows of well-defined faceted calcium-containing gall-stones leave little to the imagination in interpretation. Examples of such radiograms are now to be found in almost every X ray department, though a few years ago only a select few radiologists possessed them and knew their demonstration by X rays to be possible. The more common radiographic appearance—though to the trained eye it is as significant—is the ill-defined, thin, flaky shadow which I believe can be demonstrated in about 30 per cent. of cases in which gall-stones are present. These shadows may be obliterated by the slight movement of the gall-bladder due to body movement or visceral peristalsis, yet there may be little on the radiogram to suggest movement. They may only be seen on radiograms taken with a fraction-of-a-second exposure, and can be best demonstrated by using a cone without the Potter-Bucky diaphragm. These thin gall-bladder shadows may also be obliterated if dye enters the gall-bladder, and a normal gall-bladder may be reported, the stones being of the density of the dye concentration.

Occasionally one finds that the wall of the gall-bladder is calcified, while sometimes it is full of opaque sand which has a radiographic appearance like that of a dye-filled gall-bladder. This has led to the faulty interpretation of the cholecystogram in cases where no preliminary radiogram had been made. Where the stone is solitary, difficulty of interpretation may be experienced, but subsequent radiograms with alteration of position, and radiograms in different positions after the injection of the dye, will clear up most of the difficulties. The demonstration of gall-stone shadows on the radiogram does not necessarily account for the cause of the patient's illness, and if the complaint suggests any other lesion, this should be searched for in addition. I recorded[2] the discovery of a small carcinoma of the transverse colon in such a patient over four years ago, and since its removal she has had no further symptoms.

INJECTION AND ORAL ADMINISTRATION

Those of us who have been keen on the radiology of the gall-bladder have watched the gradual but marked improvement in the chemicals used in cholecystography. When I read my first paper on cholecystography in 1925 we were injecting sodium tetrabromphenolphthalein intravenously. This dye was toxic for a relatively large number of patients, and the gall-bladder shadow, compared with those now obtained, was relatively faint. This dye was replaced by sodium tetraiodophenolphthalein because the latter could be given in smaller quantities with lessened reaction and greater density of shadow. Gradually the oral administration of the dye was introduced and improved. At the beginning this was a very poor substitute for intravenous administration, but it was used because many radiologists would not go to the trouble or worry of intravenous injection, and many faulty radiographic reports were issued. In March, 1928, I published a paper[2] containing the evidence collected after 500 cholecystographies, in which I expressed the opinion that I regarded the intravenous method as the more accurate. Now after another four years, during which period cholecystography has become a routine procedure in the investigation of gall-bladder cases, I am still of that opinion, though I have also to acknowledge such a marked improvement in the quality and function of the dye now used for oral administration that it now falls little behind the intravenous in its results.

The arguments in favour of the intravenous method are that a known amount of dye is administered into the circulation, and the degrees of concentration of the dye in the gall-bladder is not so confusing; the gall-bladder shadow is not obscured by the shadow cast by the dye in the intestine. The hepatic function test can be made at the same time. It can be given to the patient with nausea of a degree which will not tolerate oral administration. Preferably the patient is kept under the control of a nursing staff until the radiograms are made. The oral route, on the other hand, does not necessitate hospital or nursing-home attention; the patient can take the dye at home and come up next morning for radiography, while the radiologist is saved the trouble and worry of an intravenous injection and its complications. The reactions to the dye are relatively slight or absent; in many patients no abnormal symptoms are detected, and no cathartic action from the dye occurs, though in others the dye is strongly purgative.

In the early days of oral administration the dye used often caused violent vomiting, but the present oral preparations rarely do this.

INTRAVENOUS CHOLECYSTOGRAPHY

After the preliminary examination an inspection of the anticubital fossæ is made, and that arm is selected which shows the most prominent veins.

At about 9 P.M. the patient, lying in bed, has the arm cleaned up with spirit; a tourniquet is applied to the upper arm sufficiently to cause distension of the veins, and a syringe needle is thrust into the median basilic vein. Blood spurts out of the end of the needle until a connexion is fixed into it from a 40 c.cm. syringe barrel containing a few cubic centimetres of sterile normal saline. The syringe is connected by means of a rubber tube containing a small glass connexion near the needle end. The saline is allowed to flow into the vein, the tourniquet being taken off immediately the connexion is made between the syringe and the needle. The flow of saline is slow, and when most of it has left the syringe with every indication that it has gone into the vein, 30 c.cm. of a filtered sterile solution containing 3 g. of sodium tetraiodophenolphthalein are poured down the side of the syringe barrel. If the flow ceases (and this appears to happen more often in those veins one would least expect to give rise to trouble—i.e., the large superficial veins which are readily entered and from which blood spurts out while the tourniquet is in position), the piston of the syringe can be applied and gentle pressure applied until the whole of the dye has been injected. On the slightest indication that the dye is not going into the vein the injection is stopped.

No food or drink, apart from sips of water, is allowed. The patient is brought to the radiographic department at 9 A.M., 11 A.M., and 1 P.M. on the following day, and radiograms are made of the gall-bladder area, using the same technique as in the preliminary examination. Unless the gall-bladder is visible on the screen, it is customary to always use 15″ × 12″ films, because of its variable position. Any abnormal shadows or irregularity of the gall-bladder should be investigated by taking additional radiograms in different planes. Bubbles of gas in the intestine may simulate negative gall-stone shadows. After the sixteenth-hour radiogram has been taken the patient is given a barium meal made up with Horlick's milk; a radioscopic examination is made of the stomach and duodenum, and the relation of the gall-bladder to these structures and its mobility is carefully observed on the screen during palpation.

In a paper[3] on gall-bladder radiography in 1927 I recorded non-filling of the gall-bladder in two cases in which the gall-bladder was normal, but in which an ulcer of the stomach and duodenum had been found at operation. This observation has since been made by a number of radiologists, and its possibility should be borne in mind. Only recently such an event was brought to my notice.

A patient had had a cholecystographic examination, and the radiologist had reported that the gall-bladder had failed to fill; but as the symptoms did not suggest gall-bladder disease the patient was not operated upon. He died from the perforation of a chronic ulcer on the lesser curvature.

This emphasises the importance of following up the cholecystogram with a barium meal. No clinician can be certain that it is the gall-bladder or the stomach or duodenum which is diseased. Because the patient's symptoms suggest gall-bladder disease, and because the cholecystogram suggests a normal gall-bladder, it cannot be said that organic disease is or is not present. If necessary, of course, the barium meal can be given later. In one case in which only a cholecystograph was asked for I recorded that the gall-bladder showed normal appearances, the patient was brought back to hospital within a fortnight with a perforated duodenal ulcer from which he died. At the post mortem, the cholecystographic findings of a normal gall-bladder were confirmed, and the perforated ulcer was shown. This case and the one recorded above proves that while in some cases of ulcer the gall-bladder fails to fill with dye, this cannot be depended upon. The additional radiograms taken after the barium meal may reveal gall-bladder or other shadows which have not been observed on the previous radiograms. Often one sees shadows of definite significance on one radiogram but not on another, or its significance is confirmed by alteration in position or arrangement seen on other radiograms.

ORAL CHOLECYSTOGRAPHY

The preparation which I am now using is that called opacol. It is stable, is not too unpleasant to take—very rarely causing any sickness—is readily absorbed, and gives a good contrasty shadow of the normal gall-bladder. It is British-made, and less expensive than some of the other preparations.

The patient is asked to come for a preliminary radiographic examination, after which he is given a bottle containing the opacol with the request that he has a fat-free meal—dry toast or biscuits and tea—at 6 P.M., and the whole of the contents of the bottle at 8 P.M., in half a tumbler of water, followed by a further drink of water to remove the taste from the mouth. The patient is advised to go to bed just before 8 P.M., and to return for X ray examination at 9 A.M. the following morning, having taken no food or drink apart from sips of water since 6 P.M. the previous evening.

The same technique for radiography is adopted as that already described, and the barium meal is given after the seventeenth hour from taking the dye. A further radiogram is always taken three hours after the barium meal, for this may give additional evidence on the condition of the gall-bladder, stomach, or duodenum.

With the oral preparation, the only likely ill-effect is purgation, and in many cases this is not observed. No reaction of a serious nature due to the dye has ever been recorded. The test is therefore safe, and in a very high proportion of cases (probably over 90 per cent.) accurate, particularly if the preliminary examination and the barium meal are used as part of the examination as I have described.

If the cholecystographic findings, using the oral method, are opposed to the clinical findings, further information may be gleaned by a second oral test or by intravenous administration of the dye.

NEGATIVE SHADOWS

Cholesterol and pigment gall-stones have a radio-opacity so similar to that of the bile and surrounding tissues that it is impossible to demonstrate them on the ordinary radiogram, even if the gall-bladder is radiographed after its removal from the body. When, however, the gall-bladder has been filled with bile containing tetraiodophenolphthalein, which has a greater radio-opacity than the stones, these appear as darker shadows, resembling gas-bubbles (negative shadows) within the lighter gall-bladder shadow. On the other hand, shadows of gall-stones of greater radio-opacity, which ought to have been shown on the preliminary radiograms, may now be obliterated because of the increase in density of the gall-bladder. These negative shadows are so like gas-bubbles that, unless care is used, the latter may be interpreted as gall-stones; radiograms in the lateral and semi-lateral positions will alter the relative positions of the gas-bubbles in the intestine and the gall-bladder; but negative gall-stone shadows, though they may appear to have altered in position, remain within the shadow of the gall-bladder.

CONCLUSIONS

(1) No branch of radiology requires more careful attention to technique and detail than gall-bladder radiology.

(2) The X ray examination should always include preliminary examination, cholecystography, and barium meal—in this sequence.

(3) Some gall-stones can be shown on the preliminary radiogram, and some on the cholecystogram, but there remains a proportion which cannot be shown on X ray examination. The greater

he care taken in technique, the smaller is this esidue.

(4) The radiographic demonstration of gall-stones does not necessarily mean that the lesion causing the patient's illness has been discovered. Gall-stones may exist without causing any marked symptoms, or they may produce symptoms which are atypical.

(5) The dye can be administered either by the mouth or intravenously. The former is now the best routine method of examination, though the latter is still the most accurate.

(6) In about 96 per cent. of cases non-filling of the gall-bladder indicates a pathological condition of the gall-bladder, often accompanied by stones, though these may not be shown by the radiogram.

(7) Poor filling of the gall-bladder on repeated examination also indicates a pathological condition of the gall-bladder.

(8) In a high proportion of cases a good gall-bladder shadow, which is normal in shape, size, and position, uniform in outline and density, and which contracts after a meal to a much smaller size, indicates a normal gall-bladder. A small proportion of such gall-bladders may be diseased, and even contain a small collection of stones.

(9) Any abnormality in the area of the gall-bladder before or after the gall-bladder has been filled with dye should be investigated by further radiograms taken according to the type of abnormality seen.

(10) It has been demonstrated that a large collection of gall-stones in the gall-bladder can be passed into the intestine via the ducts.

(11) Complete gall-bladder radiology enables us to give a fairly accurate and the best opinion as to the condition of the gall-bladder.

Clinical and Laboratory Notes

A CASE OF PERNICIOUS ANÆMIA

ASSOCIATED WITH MENTAL DISEASE

By Isaac Atkin, M.D. Lond., D.P.M.

ASSISTANT MEDICAL OFFICER AND PATHOLOGIST TO THE KNOWLE MENTAL HOSPITAL, FAREHAM, HANTS

Pernicious anæmia is more often a cause of mental disease than is generally recognised, and it is important to elucidate this ætiological factor as early as possible, since adequate treatment is followed by very satisfactory results. The following case illustrates this, as well as several other points of interest.

A married woman, aged 59, was admitted to the Knowle Mental Hospital under certificate on June 24th, 1931. She had never been previously certified, and there was no history of insanity in the family. The general physical condition on admission was moderately good; the heart was enlarged (old mitral disease), and there was some arterio-sclerosis, but there were no abnormalities in the nervous system. She expressed persecutory delusions directed against her husband: "He is making life a hell for me; he attempts to murder me or to drive me to suicide; he is a rotter and a drunkard." She took no interest in her environment, and her mood was one of depression.

The progress of the case was as follows:—

July 8th, 1931: Seems to be developing some insight. Thinks her accusations were not entirely justified. Still very depressed and anergic. *15th:* Remains depressed. Weeps readily.

August 5th: Complains of faintness, weakness, loss of strength. Unable to stand. No mental change.

Oct. 16th: Complains of abdominal pain, feels as if "a band were constricting her abdomen." Listless and anergic. *17th:* Skin shows lemon yellow colour. Blood count: red cells, 1,460,000; white cells, 2230; Hb., 35 per cent.; colour-index, 1·7; marked poikilocytosis and anisocytosis. Patient complains of numbness and stiffness of the lower extremities. Her gait is very unsteady and ataxic. The deep reflexes are brisk. Marked Rombergism is present. The plantar reflexes are indeterminate. No objective sensory disturbance. Patient is put on ½ lb. liver daily—half raw, half cooked—and a lemonade containing acid. hydrochlor. dil. ʒii to half a pint.

Nov. 2nd: Blood count: red cells, 3,070,000; white cells, 10,900: Hb., 45 per cent.; C.I., 0·7; some anisocytosis present. Patient unable to walk. Still complains of "numb" feelings in the back and lower extremities. *24th:* Mental improvement commencing. Does not weep. Attempting to occupy herself.

Dec. 24th: Taking more interest in her environment and is decidedly more cheerful.

Jan. 16th, 1932: Blood count: red cells, 5,400,000; white cells, 6900; Hb., 74 per cent.; C.I., 0·7; slight anisocytosis. The left knee-jerk is somewhat increased. The plantar reflexes are still indeterminate. Patient still unable to walk without aid. No sensory disturbance. *25th:* Can walk a few yards on her own. Uses a wide base.

March 19th: Blood count: red cells, 5,540,000; white cells, 6600; Hb., 90 per cent.; C.I., 0·8. *24th:* Skin and mucous membranes good colour. Gait steady, and she can walk unsupported, though still uses a somewhat wide base. The plantar reflexes are flexor. There is a little spasticity in the muscles, and the left knee-jerk remains exaggerated. *30th:* Discharged on one month's trial.

April 27th: Discharged off trial.

That pernicious anæmia can cause mental disease is now an accepted fact. Psychogenic factors can of course be elicited in these cases, as indeed in every type of mental disease; but these factors are only a condition and would not of themselves bring about a mental disturbance. In this particular case the patient had repressed into her unconscious hostile feelings directed against her husband (for which indeed there may have been some justification) and the impaired physical state, by lowering the power of the repressing psychic forces, permitted these feelings to appear in the conscious as persecutory delusions.

Mental symptoms may appear before the condition of pernicious anæmia is recognisable clinically, and may be so prominent that the underlying blood state is overlooked. Hence the importance of an early blood examination.

Of special interest here is the development of early signs of subacute combined degeneration of the spinal cord, and their amelioration under liver treatment. According to McAlpine [1] the effect of liver on the neurological signs is variable, and he states that improvement is only slight once the Babinski reflex appears. In the present case the neurological symptoms were attacked early—no Babinski sign having been obtained—and this may account for the satisfactory response. C. C. Ungley and M. M. Suzman [2] lay stress on the importance of instituting liver therapy as soon as possible.

In those cases of pernicious anæmia with psychotic symptoms that develop the signs of subacute combined degeneration there is a danger of diagnosing the latter as "functional." In fact the possibility of hysterical astasia-abasia was raised in this case at first. The blood examination settled this point at once.

I wish to thank the medical superintendent, Dr. J. L. Jackson, for permission to publish this case.

ANEURYSM OF THE AORTIC ARCH

TWENTY-NINE YEARS SURVIVAL

By M. J. Stewart, M.B. Glasg., F.R.C.P. Lond.
PROFESSOR OF PATHOLOGY IN THE UNIVERSITY OF LEEDS

AND

H. G. Garland, M.D. Leeds, M.R.C.P. Lond.
MEDICAL TUTOR AND REGISTRAR

In January, 1899, a man, aged 33, was admitted to the General Infirmary at Leeds under Dr. A. G. Barrs, complaining of cough, pain in the front and right side of the chest, and in the shoulders and back of four weeks' duration.

He had had "rheumatism" in the shoulders three years and an ulcer of the leg eight months before. He had had malaria at the age of 18, but denied having had syphilis. His occupation, that of packer and porter, entailed very heavy work.

There was notable pulsation in the right chest, most marked in the second interspace where it was expansile in character. In this region there was a large area of dullness and marked tenderness over the inner ends of the second and third left interspaces. Tracheal tug was present but the vocal cords were normal. Aortic systolic and diastolic bruits were heard. Urine normal. The diagnosis was aneurysm of the first part of the aorta. The patient was put upon iodide treatment and sent home after two months.

In March, 1928, 29 years later, he was readmitted under Dr. J. le F. C. Burrow with weakness, wasting, and anorexia of one year's duration. He had occasional vomiting and some difficulty in walking in the dark, and there had recently been some frequency of micturition.

Since his discharge from the infirmary in March, 1899, he had led a perfectly normal life. He had pneumonia in 1905 and made an uninterrupted recovery. With this exception he had been at work as a janitor during the whole interval of 29 years, and the only symptom he ever complained of was a slight unproductive cough. He was never short of breath. Of his two sons one was killed in the war; the other is married, and his wife's only pregnancy terminated in stillbirth. This son is himself in excellent health. The patient had been teetotal during the whole of the period.

On examination (March 24th, 1928) the apex-beat was normal. There was pulsation to the right of the manubrium with an area of dullness, an aortic systolic bruit, and an accentuated aortic second sound. Blood pressure was 106/80 mm. Hg, pulse 88–100, temperature normal, respirations 24. The blood Wassermann reaction was negative. The pupils were sluggish to light, knee-jerks sluggish, and ankle-jerks absent. A blood count showed red cells, 4,530,000; hæmoglobin, 50 per cent.; colour-index, 0·56; white cells, 9100. X ray examination revealed a very large aneurysm mainly in the right side of the chest, the wall of which appeared to contain calcareous material. The patient died one week after admission.

Post-mortem examination.—There was a large aneurysm of long standing with enormously thickened and partly calcified walls in the upper part of the chest. It was mainly median in position but extended rather more to the right than to the left. Roughly globular in form, it measured about 4½ in. from above downwards, 5 in. transversely, and 3½ in. in antero-posterior diameter. It was adherent in front to the chest wall, and its upper border was about 5 in. below the level of the thyroid cartilage. After fixation of the thoracic contents en masse a series of transverse sections were made. These showed that the aneurysm was of saccular type, springing by a rounded orifice rather more than ½ in. in diameter from a point near the junction of the first and second parts of the aortic arch. The outer part of the aneurysmal wall was densely calcareous, and the interior of the sac was largely occupied by dense laminated thrombus. The unobliterated portion, which communicated directly with the aorta by the aperture above-mentioned, measured approximately 2 by 2 by 1 in. The first and second portions of the thoracic aorta were much dilated and their walls grossly diseased, partly old syphilitic scarring but mainly atheroma with calcification. There was also early atheroma in the terminal 2 in. of the abdominal aorta.

There was a large malignant tumour (hypernephroma) in the upper part of the right kidney with involvement by direct extension of the right suprarenal and right lobe of the liver.

Careful examination revealed a doubtful scar on the penis, and there was an old tuberculous (?) lesion of the left wrist.

The case is a remarkable example of prolonged survival and continued good health in face of a large intrathoracic aneurysm. When the patient was first in hospital in 1899 it was quite clear that he had a large aneurysm probably of the first part of the aortic arch. A gloomy view of the prognosis was taken at the time, and he was sent home with very little hope of recovery. He lived for 29 years thereafter, and for nearly the whole of this period not only enjoyed good health but was able to continue in full work as a janitor. At autopsy there was no evidence that the aneurysm had itself contributed to the fatal issue. Though still present, it had enormously thickened walls with dense calcification in the outer layers. Death resulted from a hypernephroma of the right kidney with involvement of the adrenal and liver.

We beg to express our indebtedness to Dr. Barrs and Dr. Burrow for permission to make use of the clinical notes of this case.

A CASE OF ALCOHOLIC CIRRHOSIS

TREATED ON THE PRINCIPLE OF THE TALMA-MORISON OPERATION

By J. E. Piercy, F.R.C.S. Edin.
SENIOR ASSISTANT MEDICAL OFFICER ST. ANDREW'S HOSPITAL, BOW

A woman, aged 52, was admitted to St. Andrew's Hospital, Bow, under my care on Dec. 31st, 1928.

History.—Her trouble began in the early months of 1928 with nausea, particularly in the morning, and loss of appetite. This was soon followed by morning vomiting and general lassitude. The weakness increased and she began to lose weight, noticing that her arms, legs, and face were much thinner. In May, 1928, she found that her abdomen had become swollen, the swelling increasing with great rapidity. She became progressively weaker and finally was unable to climb stairs. By December, 1928, she was confined to bed. She had spent the greater part of her life employed in a public-house and was a heavy drinker of spirits, imbibing approximately a bottle of gin daily. Her usual weight was 12 st. 3 lb.

On admission the abdomen was greatly distended, leaking a straw-coloured ascitic fluid from an umbilical hernia the size of an orange. There were distended veins coursing over the anterior abdominal wall and chest, limbs and body wasted, and feet cold and œdematous. The leaking rupture was acting as a safety-valve, and the patient discharged herself on Jan. 21st, 1929. Within three weeks she was readmitted having again become distended. Paracentesis abdominis was performed and 15 pints of straw-coloured fluid were withdrawn. In the following few months paracentesis was performed on seven occasions. She was now very weak and emaciated, her face was sallow and drawn, her eyes sunken, and the conjunctivæ were slightly jaundiced. Her weight was now just under 7 st. The last paracentesis had drained 21 pints, but within seven days she was again distended. She was also troubled with intractable diarrhœa.

This picture of alcoholic cirrhosis and associated gastro-enteritis fitted perfectly with the pathology of the condition, the portal or multilobular cirrhosis. The degeneration of liver cells and the formation of fibrous tissues surrounding and compressing the intra-hepatic branches of the portal vein was attributable to the action of the alcohol in producing gastro-enteritis and consequent toxæmia, and to its direct action on the liver. This gradual obstruction of the intrahepatic portal venules had given rise to congestion followed by ascites. The alcohol and the toxins produced by the gastro-enteritis perhaps also increased the flow of peritoneal fluid by irritation of the peritoneum—a form of aseptic peritonitis.

To aid the normal venous connexions between the systemic and portal circulations, an accessory venous circulation can be formed by producing adhesions between the greater omentum, liver and spleen, and the parietes. in this way overcoming the portal obstruction. With this end in view, operation was undertaken after full explanation of the risk entailed.

Operation.—An oblique incision was made from the costal margin at the lateral aspect of the left rectus and running downwards to the lateral aspect of the right rectus well below the umbilicus. The recti were well separated and the peritoneal cavity was widely opened. The fluid was drained and mopped away. The liver was approximately normal in size. its surface being irregular and covered by a thick white coating. There was perisplenitis and enlargement of the spleen. The surfaces of these were scrubbed with a hard hand-brush, as was also the peritoneum adjoining them. Hæmorrhage was severe. The greater portion of the gastro-colic omentum was brought through and buried between the posterior sheath and the recti. Suprapubic drainage was performed. a glass tube being used. The peritoneum was then closed by interrupted sutures. The tube was removed on the fourth day. the wound healed on the eleventh day. Three weeks later paracentesis was performed, 4½ pints draining. There was no further tapping.

On August 1st, 1929, the patient was readmitted with a strangulated umbilical hernia, the small intestine having slipped into the sac previously occupied by the fluid.

Second operation.—The small bowel was found to be gangrenous and enterectomy was performd, two feet of small intestine being removed with end-to-end anastomosis. The liver, spleen, and omentum were firmly adherent to the parietes. Hanging to the intraperitoneal portion of the omentum there were many mucoid pear-shaped globules the size of small grapes. Radical cure was performed for the hernia. Convalescence was uninterrupted and the patient discharged on the 23rd day.

From September, 1929, until Jan. 1st, 1932, the patient was at work daily, her weight being 12 st. 2 lb. She had occasional attacks of distension which passed off after a few days. She was taking two ports and two glasses of stout a day. Appetite and bowels normal. On April 27th, 1932, she was readmitted with the history of four months' jaundice. She had had an attack of hæmatemesis three days before admission. She was deeply jaundiced and there was bile and albumin in the urine. The pulse was feeble and irregular, the chest full of rhonchi and crepitations. Blood was found in the stools. Death occurred two days after admission.

Post-mortem examination.—The body was well covered, the skin deeply jaundiced. The liver was small, firm, deeply stained and shrunken, its surface being irregular with very little sign of any compensatory hyperplasia. The spleen was firm and enlarged, both organs being firmly adherent to the parietes. The greater omentum was firmly consolidated with the anterior abdominal wall. There was an acute gastritis with small erosions of the mucous membrane. The kidneys were small and granular. The lungs were congested and the heart was soft and friable.

The noteworthy features of this case are: (1) that the formation of widespread adhesions produced a permanent cure of the ascites in an advanced case; (2) that enterectomy was later successfully performed with normal healing of the intestine without production of the ascites; (3) that the hæmatemesis just prior to death was due to erosion of the stomach, not to rupture of the gastro-œsophageal veins; (4) that the spread of fibrous tissue encroached on the bile-ducts and led to an intrahepatic obstructive jaundice; (5) that there was very little sign of any compensatory hyperplasia of the liver tissue.

BRITISH MEDICAL ASSOCIATION

CENTENARY MEETING IN LONDON

SECTION OF PUBLIC HEALTH

THIS section opened with Sir GEORGE NEWMAN'S presidential address on the rôle of the private practitioner in relation to the progress of preventive medicine during the past 100 years and his influence on prevention at the present day.

The Practitioner and Preventive Medicine

Coincident with the passing of the Reform Bill, the growth of knowledge since 1832, he said, marked an epoch unequalled in any previous age. In the passage from central to local government and from aristocratic to democratic institutions, the resulting great social transition. as shown by the ultimate State control by the people, had led to the harvest of philanthropic effort in the cause of public health.

Two dominant factors were to be noted in that steady march of progress: firstly, the expansion of science and the application of scientific method; secondly, the habit of coöperation to which individualism had given place. In a review of the stages through which modern preventive medicine had passed, it was natural to dwell on the improvement brought about in their environment by the great sanitarians of the past in securing such benefits as the general use of pure water-supplies; the isolation of the sick; the removal of nuisances; housing reform; main drainage and the disposal and treatment of sewage; food inspection; factory acts; and vital statistics.

A feature of the inter-relationship of medicine and public health had been the endeavour of 18th century practitioners, Glisson, Sydenham, and others, whose example stimulated those who came after in the 19th century to search out the dependence of disease on environment, to introduce notification and the isolation of infectious disease. By their study of work in the factory began industrial welfare—to them likewise was due the reform of midwifery, and the inquiry into child sickness and mortality, and the establishing of the dispensary. It was by their support of vaccination that the principles of immunity became realised, and through them began British epidemiology.

As the study of anæsthetics had given surgery its great advance, so had new means of measurement and methods of physical diagnosis aided the physician in the differentiation of disease. There came to light too the importance of personal hygiene, and by the observations of notable pioneers, Richardson, Budd, and others, had been interpreted the association of certain infectious diseases with the means of spread. thus leading to their prevention, as in the case of typhoid fever, cholera, and tuberculosis. As the result of the new poor-law in 1834, there had been opened up the relief of the deplorable insanitary conditions then existing. By that step medicine had become preventive as well as curative, and thus some 4000 practitioners had been called upon to take part in the State service of the prevention of disease. The President traced the development of legislation from that time until 1911, when through the passing of the Insurance Act means of prevention as well as the treatment of disease were brought under the control of the practitioner. His advice and aid were now sought by the insured at the outset of illness, and much permanent and temporary ill-health was averted by timely measures. Prevention in the liberal sense had been effectively encouraged by health insurance. Far from a "gulf" existing between preventive and curative medicine, too strong emphasis could not be laid on their close mutual relationship; they were so interdependent and complementary as to be inseparable.

Measles Prophylaxis

Prof. C. C. OKELL (London) opened a discussion on the attenuation and prevention of measles. He said that the knowledge requisite for checking much of the loss of life and disability due to measles had long been available, but little effort had yet been made to apply it in this country. Unfortunately next to nothing was known of the ætiology of the disease. Among animals only the monkey was at all susceptible, so that an immune serum could only be got from human beings, who had had the disease. Although some unexplained failures had occurred, the bulk of experience had lent support to the value of convalescent serum as an effective prophylactic, success being claimed in 80 to 90 per cent. of cases. For public health purposes the use of "adult" rather than "convalescent" serum would be much more convenient if it was found to be equally effective. Although in theory the amount of antibody became much reduced with lapse of time after an attack, there was, nevertheless, evidence that adult serum was of use. In the absence of a greatly needed central organisation to further the work, it was difficult to collect sufficient serum for extensive trial.

The donor experienced a tonic effect on the removal of 200–300 c.cm. of blood, and Prof. Okell described the apparatus he had devised for blood-letting.[1] The scheme he envisaged for the collection of serum on a large scale would possibly claim the services of a full-time medical officer; moreover, the treatment and preparation of the serum for human use demanded experience and technical knowledge. The present limited supply of serum should be reserved for children under the age of 4, who were not only more susceptible but also far more easily protected than older children. While passive immunity could be given for a short period, subsequent exposure to infection might still determine an attack. The general belief that measles could be modified by doses of serum insufficient to prevent the disease could not be accepted without more conclusive evidence, since sometimes trivial attacks occurred in untreated children. Prof. Okell suggested as points for discussion whether the completely protected child might still be infectious to others, and whether sterile human serum injected into children ever gave rise to local reactions.

Dr. DAVID NABARRO (London) said that human convalescent serum had proved far more reliable than any animal serum, and gave protection in over 95 per cent. of cases. More extensive preparation and wider use of the serum was desirable. The difficulty of obtaining a sufficient supply of serum had been met elsewhere and could be overcome in England, especially if adult serum proved of value. He preferred to collect convalescents' blood at 7 to 14 days after defervescence. The dosage ranged from 3 c.cm. for patients under 1 year, increasing by 1 c.cm. for each year up to 7 c.cm. for those over 5 years, 10 c.cm. at 10 to 12 years, and 12 c.cm. for adults. Except for a few cases in older children of transient erythema and rise of temperature to 100° or 101° F., the effects from injection of properly prepared serum were not to be feared, and being of human origin, the serum did not cause anaphylaxis or reactions. Its use, however, in young infants under 6 months was not advised; they were not usually susceptible, and injections might cause rise of temperature and malaise. If complete protection was desired, with passive immunity for two to four weeks, serum should be given on or before the fifth day of incubation; but if a mild or modified attack, with subsequent lasting immunity, injection should be given between the sixth and ninth days of incubation. The so-called "sero-attenuation" was much to be preferred, as the condition might be apyrexial with only transient rash, and it was probably non-infective unless there was coryza or bronchitis; whereas the passive immunity by "sero-prevention" was so short that further protection became necessary during an epidemic. After the ninth day of incubation, protection by serum could not be expected, and serum treatment of measles during attack was of no value. Dr. Nabarro strongly emphasised the need for official action in arranging for preparation and distribution of serum on a sufficient scale.

Dr. WILLIAM GUNN (London) pointed out the importance of study of the epidemiology and clinical features of measles, combined with inquiry into the conditions calling for the use of serum prophylaxis, as well as machinery for a survey of case records, if a just estimate of the value of any special line of treatment was to be made. Exact deductions from statistics on measles morbidity were not possible in the absence of compulsory notification of the disease. He referred to the change of attitude to infectious disease in the past 30 years as an epitome of the history of the reaction of the human race to such disease. The sacrifices and libations of our ancestors, who fled to escape an epidemic, closely corresponded to the rites observed only in recent years in the pouring out of carbolic and burning of sulphur in the belief that thus spread of infection would be averted. In was in 1920 that public health authorities gave up purely preventive measures of control, realising that an epidemic would continue so long as there was susceptible material remaining. Attempts were now made to postpone attacks until a later age or season was reached, to provide medical and nursing supervision in the home, and hospital treatment for severe cases. Dr. Gunn described his experiences in serum prophylaxis in the 1927–28 and 1929–30 measles epidemics. After trying many sera he regarded convalescent human serum as the only prophylactic to give uniform results free from harmful effect.

He gave the serum in minimum doses of 5 c.cm. to all cases. The dose was increased according to age, the number of c.cm. being twice the years of age. Intramuscular injection soon after contact with infection and before the fifth day gave complete temporary protection; the same dosage given between the fifth and ninth day resulted in an attenuated attack.

In the course of five ward outbreaks at the Western Hospital, the last hundred contacts had thus been completely protected. Further controlled investigations were required before accurate conclusions could be formed on the effect of serum prophylaxis. Steps were now being taken to ascertain the value of adult serum, and, if this proved satisfactory, it was proposed to arrange for the pooling of serum from volunteers in order to furnish a supply for use in hospitals and private practice. It was necessary to take care to select donors who had really had measles.

A total of over 24,000 c.cm. of adult serum had been obtained, averaging over 100 c.cm. per donor, and over 2000 doses had been issued to L.C.C. general and special hospitals since December, 1931, and to children's homes and residential schools since March, 1932.

---

[1] See THE LANCET, Sept. 3rd, p. 514.

Results of administration of adult serum in hospitals and residential schools had shown that 77·2 per cent. were completely protected, and that 17·3 per cent. had attenuated attacks; in 2·9 per cent. there was no reduction in severity. Of those under 3 years, 81·2 per cent. were protected; at 3 to 5 years 69·2 per cent.; and at over 5 years the protection rate was 89 per cent. In children's homes and residential schools 85 per cent. of those injected were protected; 14 per cent. had modified attacks; and 1 per cent. showed no result from injections.

A full account of the work of preparation of material and the procedure adopted would appear in the report of the Medical Officer of Health for London on the measles epidemic of 1931–32.

Dr. Gunn's personal impression was that though convalescent serum yielded better protection than adult serum in the doses given, there was little to choose between the two when modification of the attack was desired. The dosage of adult serum advised was double that of convalescent serum—namely, a minimum of 10 c.cm. increased according to age. As to the points raised by Prof. Okell, antibacterial serum and normal horse serum both had some relieving effect in measles, as also in acute respiratory affections. The carrier state was unknown in measles and the contact without clinical attack did not appear to harbour the virus. A modified attack, in which the patient had less catarrh, was less likely to convey infection than a normal attack; but, when transmission did occur, the disease bred true and might give rise to quite severe attacks. Although French writers had recorded severe reactions following measles serum injection, he had never observed more than vague local tenderness and occasional slight pyrexia on the evening of injection—which he regarded as probably of psychic origin.

Dr. T. M. **Hunter** (Glasgow) said that in the Glasgow epidemic of 1931–32 nearly 3000 c.cm. of serum were procured from 54 donors, who had become available when the epidemic was well advanced during November, 1931. Collection was made on the seventh to tenth day of normal temperature, and after treatment with trikresol, the serum was stored in an ice-chest. Disregarding certain doubtful cases there remained 233 contacts who had received convalescent serum. Of these, 185 had escaped attack, yielding 80 per cent. completely protected; 36 had had attenuated attacks. Eight had had "mild" attacks—i.e., slightly more definite than the attenuated form—and four developed "classical" measles; but as the rash had developed at one to five days after injection, the serum had been too late for prevention. Out of 32 control contacts, not given serum, 23 got typical measles.

Dr. Hunter then discussed the various factors bearing on the investigation, the day of injection of serum, the age of the serum used, the age of injected child, the amount of serum given, and the duration of immunity. He believed that the best use to make of convalescent serum was not to give temporary prevention by large doses, but by the 5 c.cm. dose to change a possible fatal attack into a modified one without complication, and thus to ensure lasting immunity.

DISCUSSION

Sir **George Newman** contrasted the encouraging constructive work of the last few years with the previous helplessness experienced in dealing with measles. There were formidable administrative difficulties in the way of a rapid adoption of measles prophylaxis but steps were, however, being taken in the Ministry of Health to help forward the movement.

Dr. J. I. **Collier** (London) described the important part played by the general practitioner who first saw the case and treated it. The patient was only sent into hospital if complications arose. Of the 60,000 cases of measles in the 1929–30 epidemic, 6000 were treated in hospital and of those about one-third were admitted with complications. The hospitals were, he said, really treating only the complications of measles and not the disease itself. Since serum was of use only before the ninth day of incubation, every case of measles seen in private practice, at the stage when diagnosis was possible, was too late for serum treatment. There was, he thought, much guesswork in the immunisation of contacts, for which 95 per cent. protection had been claimed.

In a series of 7000 children at the High Wood Hospital in ten years, there arose 16 primary cases of measles, and though no active preventive measures had been taken, only five contacts were subsequently attacked. If all the hundreds of susceptible contacts had been given serum as advocated, almost 100 per cent. protection could have been claimed. Dr. P. Stocks had shown that under the best conditions serum prophylaxis could only reduce an epidemic by 13 per cent., and the conditions governing even that small percentage, Dr. Collier stated, were hopeless in practice. From Dr. A. Hoyne's good results with amidopyrin, which he had himself confirmed both in practice and in hospital, he regarded the use of the drug in the pure state as the most valuable method of treating and attenuating measles. Whilst convalescent serum in ward outbreaks was of value for ensuring a modified attack, and only exceptionally for producing protection, Dr. Collier held that it had no value in the control of epidemics.

Dr. A. S. M. **Macgregor** (Glasgow) confirmed Dr. Hunter's impressions of the value of prophylactic serum in Glasgow. There was, he said, adequate supply of serum in Scotland, as most adults had had the disease and readily supplied their sera.

Dr. C. **Killick Millard** (Leicester) showed charts of measles and whooping-cough mortality in Leicester during the past thirty years, demonstrating the marked fall of the quinquennial average mortality from measles since 1917 in contrast to the continued high mortality from whooping-cough.

Dr. W. G. **Savage** (Somerset) said that in Somerset also there had been a fall in measles but not in whooping-cough mortality. He advocated measures directed to delaying or attenuating the attack, as there was little chance of preventing measles. For those under 5 years, the most exposed to the severe type, protection against early attack and postponement till after 7 years should be the objective.

Dr. D. S. **Sutherland** (Manchester) said that voluntary donors receiving a fee of three guineas for collection of serum should previously be examined by the public health department for verification of diagnosis to avoid the chance of their having had only rubella.

Dr. R. A. **Glegg** (East Sussex) urged the necessity of active health instruction and propaganda by health visitors as a means of obtaining offers of convalescent serum.

REPLY

Prof. **Okell** stressed the importance of more analysed statistics. The evidence in favour of convalescent serum should be marshalled by a statistician. Although the control of measles on a large scale was, he felt, quite impracticable, the demands for serum were often most urgent. There was need of an emergency scheme even for a limited supply.

Mental Capacity of Children in Relation to Environmental Conditions

Dr. J. RIDDELL (Stirling) gave the results of an investigation undertaken amongst over 1600 Falkirk and Stirling children, including a group of 955 of 9 years (479 boys and 476 girls) and another group of 683 of 13 years (346 boys and 337 girls). The groups of children were arranged in four categories according to mental capacity—advanced, normal, retarded, and very retarded. Among the advanced were a number of bright children with defective speech; and among the very retarded, a large percentage had visual defect or defective hearing. In estimating as to whether a child was fit for a school class, and was suitable according to age, information was supplied by the school teachers and headmasters. It was noted that in the course of their school life girls moved more quickly from lower to higher classes than boys. With regard to observations on environmental conditions, and the study of other points in relation to mental capacity, attention was given to the influence of the following factors :—

(1) *School attendance.*—As to the effect of lateness in going to school; the changing of schools; and irregular attendance. Children in the 9-year group were found to suffer more materially by irregular attendance than those in 13 year age-group and more so among girls than boys. The children of parents of sedentary occupation attended better than those who followed more active employment.

(2) *Nutrition.*—There was a steady decline in height and weight of children to be noted in passing down through the various divisions of mental capacity—i.e., retarded children were smaller and lighter than their fellows.

(3) *Rest in bed at night.*—Little reliable information was forthcoming which could be satisfactorily correlated with effect on mental capacity.

(4) *Environment.*—There was a definite tendency for an increased percentage to appear in the retarded groups of children who also lived in overcrowded conditions—i.e., more than two persons living in one room—whilst those living in less crowded conditions were in a minority among the retarded children.

(5) *Occupation of parents.*—There were more children of manual labourers in the retarded classes where the children were also the most dirty and ill-clothed. On the other hand there were more children of parents with sedentary occupation in the advanced classes; they were also taller and heavier than those whose parents were engaged in manual work. The dull child was to be found among the manual labouring class, living in only one or two apartments, whereas the cleanly child of good mental attainment was more common among the sedentary workers.

(6) *Physical defects.*—All pulmonary and organic cardiac defects tended to cause mental retardation, whereas minor defects, such as enlarged tonsils and adenoids, were found to have apparently little influence.

From the results of his investigations Dr. Riddell concluded that conditions of home environment and nutrition must be regarded as important factors affecting the mental capacity of children.

SECTIONS OF RADIOLOGY AND MEDICINE

AT a combined meeting of these sections the chair was taken by Prof. A. J. HALL (Sheffield), and Dr. STANLEY MELVILLE opened a discussion on

Radiology in Diseases of the Lungs

The place of radiology in lung disease was, he said, now supremely important. As Salusbury MacNalty had said, the pendulum has swung too far and some enthusiasts diagnosed pulmonary tuberculosis solely on X ray evidence, ignoring orthodox physical examination. Definite infiltration could be demonstrated upon a film at an early stage, often before definite physical signs were present, and consistently negative evidence for some months proved the absence of pulmonary tuberculosis. When physical signs were present the pictures usually showed much more extensive disease than the physical examination. As a result of long experience at the Brompton Hospital Dr. Melville believed that in a vast majority of cases the bacillus entered the lung by aspiration, and that any further invasion in the adult was exogenous. In the infant the result of infection depended upon the initial dosage and the degree of resistance, varying from rapidly fatal caseous broncho-pneumonia to a primary focus in the lymphoid tissue round the smaller bronchi. The resulting response in the tracheo-bronchial glands might calcify or might caseate or burst into a bronchial blood-vessel, leading to an aspiration infection or a miliary tuberculosis. The focal reaction to a tuberculous gland might be quite evanescent, or might persist or recur. There was usually some pyrexia and malaise and the infant reacted positively to tuberculin. The skiagram showed a wedge-shaped area extending from the inflamed gland into the surrounding tissue. After a time this area disappeared, and the diagnosis of "pulmonary tuberculosis" was not justified.

Dr. Melville pressed for the general adoption of the word "infiltration" as describing a parenchymatous invasion by the tubercle bacillus, and for the wider use of the term "fibrosis" to describe a condition of healing in which there was definite deviation of the mediastinal content to the affected side. Expressions such as "active" or "healed" should, he urged, be used with caution if at all, as such conditions were clinical rather than radiological. The advantages of the upright position for chest radiography were that fluid levels could be seen and the early screening could be done and the tube racked out for long-distance radiography without moving the patient. The disadvantages were that it was not possible to centre the tube with such accuracy as to obtain an identical picture months or even years later; that it was impossible to deal with an ill patient; and that the female breast threw a much more obstructed shadow in the upright than in the recumbent position. At the Brompton Hospital the difficulty had been solved by cutting a hole in the floor. Dr. Melville showed slides illustrating this apparatus.

PULMONARY TUBERCULOSIS

Dr. R. A. YOUNG said that radiology had become important not only in diagnosis but in the estimation of the extent of the disease and in its treatment. Exaggerated claims made on its behalf were not infrequently the fault of the general practitioner or the physician, who sometimes made unfair demands. To suggest that radiological examination should replace clinical examination was a harmful and unfortunate attitude. Radiological evidence was only one form of physical examination, complementary to ordinary methods and not competitive with them. Careful clinical observations had never been more necessary or helpful, but unfortunately patients shared with the public a deeply implanted belief in instrumental and laboratory investigation, forgetting the presence of the human element and instrumental error. The value of radiological information must depend upon the efficiency of the apparatus and the experience of the person who interpreted the films. The clinician should not ask a radiologist to report on a case of which he did not know the clinical features and history; nor to exclude tuberculosis on one examination. When tuberculosis was suspected it was necessary to collect as much evidence as possible; the history should be taken very fully and was often the best pointer to the diagnosis, especially a temperature record was available. Dr. Young id that he often re-examined the patient with the m in view. The more experience the radiologist d of chest work, the more guarded were his reports, it if he were taken into consultation over the inical features he could often give fruitful explanaons of what was obscure. There was need for much eater relation between radiographic appearances id post-mortem findings than existed at present efore films could be interpreted in pathological rms, or conclusions could be drawn concerning the iset of tuberculous lesions in the chest. The eaker said he was very reluctant to describe ultiple rounded shadows as miliary tuberculosis ithout some clinical support. He disliked the term infiltration" and preferred to use the word deposit," qualified by "old" or "recent." He ipported Dr. Melville's plea for a standardised rm of a report and for agreement on nomenclature. ladiology gave more help in assessing the extent, ge, and character of the lesions, than on their etiology or their quiescence or activity. It gave aluable information on the state of cavities, the resence of effusions, and the displacement of heart, rachea, or diaphragm.

BRONCHIECTASIS AND LUNG ABSCESS

Dr. F. G. **Chandler** said that radiology had shown no more dramatic developments than in these two conditions. With lipiodol the existence, extent, and position of non-obstructive bronchiectasis could be proved and the integrity of the opposite side could be tested. The bronchiectatic area might escape the oil, and careful technique and critical evaluation of the pictures was needed. Radiology also helped in showing the chronic atelectatic lobe and the degree of diaphragmatic rise after phrenic evulsion and of collapse in artificial pneumothorax.

The radiographic picture alone might serve to differentiate abscess from bronchiectasis and new growth by showing a fluid level, but sometimes it only showed a diffuse obscured area. Lipiodol usually stopped short at the periphery of the affected area, but sometimes flowed into the abscess cavity. The distinction between abscess and breaking-down growth might be difficult if radiography were too long delayed. It was said, however, that iodised oil showed a more conical shape at the site of obstruction with a growth than with an abscess. It was rare for the patient with an abscess not to cough up pus, but in a malignant abscess there might be complete obstruction even though an enormous abscess was present. Neither lipiodol nor the position or pattern of the shadow, nor the failure to expectorate the pus, nor bronchoscopy could be relied on in all cases, and diagnosis might be a matter of clinical judgment. In any doubt it was better to operate, and exploratory thoracotomy must be added to the list of diagnostic procedures. Accurate localisation was essential for the successful operative treatment of lung abscess and was usually impossible without radiography. Antero-posterior and lateral views must be taken, but stereoscopy was of less value in this condition than in others.

COLLAPSE TREATMENT

Dr. L. S. T. **Burrell** stressed the importance of coöperation between the clinician and the radiologist, and said that the radiologist should have clinical knowledge of the patient, because even with the most careful radiological examination it was sometimes difficult to detect where the pneumothorax was. There was a tendency to conduct pneumothorax according to the radiographic findings; while the radiogram had great value the condition of the patient and his symptoms were even more valuable. Patients who had been treated some ten years ago when the position of the mediastinum had been ignored had done extremely well. Nowadays, guided by the radiogram, it was common to give very small refills, and the pendulum had swung a little too far. He advised the use of the radiogram to show whether there was any danger of adhesions forming; and the extent and rate of collapse and expansion. Adhesions could only be localised by radiology, and before introducing a thoracoscope and cautery it was necessary to get a definite localisation by rotating the patient. The dangers of thoracoplasty had been reduced, but before it was performed the clinician should see a radiogram of the lungs, especially of the opposite lung. An indispensable guide to the probability of success was furnished by the condition of both lungs. It was dangerous to raise or lower pressure by oleothorax entirely on the radiological findings.

LIPIODOL

Dr. J. **Duncan White** (Edinburgh) said that lipiodol might be injected by one of four routes: supraglottal, through the cricothyroid membrane, trans-nasal, or by the bronchoscope. The route of choice depended on the particular case and the manipulative skill of the operator; moreover, many patients would be suffering from cough and expectoration, and in these patients it was often very difficult to inject anything into the air passages. The preliminary radiogram, which was essential, would show which part of the lung tissue required investigation, and this knowledge might determine the choice of route. The speaker said that he preferred the supraglottal route for routine purposes; the patient must realise that he could breathe perfectly easily with the mouth open and the tongue protruded. The less the display of equipment, the easier the examination. Properly carried out, the injection through the cricothyroid membrane was quite safe. If, however, the radiogram showed that the most pronounced lesions were in the upper lobe, the trans-nasal route was indicated: the patient should be arranged on the radiographic couch in the partial Trendelenburg position. If the bronchoscope was being used, the oil should be injected through it, but as a route its use was unnecessarily severe.

Lipiodol was invaluable in bronchiectasis, as it would show up the general cylindrical dilatation of the basal bronchioles. Dr. White said that he had been unable to observe the differentiating point which Dr. Chandler had mentioned between bronchial abscess and bronchial stenosis due to neoplasm. Before any treatment for lung abscess was carried out it was essential that the extent of the bronchitic change should be determined. Lipiodol would often show secondary bronchitis in the contralateral lung when clinical methods had failed to detect it. Finally, it would often give valuable information of the progress of healing in artificial pneumothorax, phrenicotomy, or thoracoplasty, and would show the size of the cavities before treatment. In chronic empyæma it would determine the extent of the sinuses, particularly when they extended below the level of the diaphragm.

DISCUSSION

Dr. E. W. **Twining** (Manchester) spoke of the necessity for standardisation of technique and of nomenclature. There was a demand, largely from public authorities and silicosis committees, for films which were strictly comparable one with another.

Standardisation should not be overdone; a film which showed abundant lung detail was not necessarily the best for mediastinal lesions. He preferred a film where the bifurcation of the trachea and the left bronchus could just be distinguished. There was a tendency to over-softness and under-exposure by enthusiasts apparently anxious to record hypothetical infiltrations. The radiologist should not adopt such terms as "exudative," "productive," or "cavernous" foci without verifying their meanings in the post-mortem room. A series of films so verified was a priceless heritage. These were some of the terms which had been evolved in Germany on the basis of post-mortem findings, and they deserved recognition. He condemned the idea that a small, barely visible focus might develop into a spreading tuberculous lesion. Tuberculosis advanced by a series of catastrophes, each involving a considerable extent of lung, and the smaller a lesion was the less likely was it to be early.

Dr. J. V. SPARKS showed several sections of typical asbestosis bodies. The radiographic examination, he said, was very important in conjunction with a comparative examination on previous data; many firms had their employees radiographed on engagement. In advanced cases the diaphragm movement was limited and the outline was indistinct and sometimes uneven, with clouding of the costo-phrenic angles and thickening of the pleura. The relative scarcity of visible change did not mean that the condition was less severe than silicosis.

The PRESIDENT paid tribute to the efficiency of the work on silicosis in Johannesburg and the close coöperation there between radiologists and physicians.

Prof. LYLE CUMMINS (Cardiff) described silicotic lung changes and illustrated them with slides, some from South Africa.

Dr. W. R. F. COLLIS traced the development of primary tuberculosis according to the German interpretation. After a six weeks' incubation period some reaction to tuberculin was noted, the "paratubercular" signs appeared and signs of hilus tuberculosis could be seen in the radiograms. Swellings in the hilar glands were seen in about 30 per cent.

Dr. MELVILLE replied.

SECTION OF ORTHOPÆDICS

Mr. R. C. ELMSLIE (London) presided over the session of this section when Mr. HARRY PLATT (Manchester) opened a discussion on

Colles's Fracture.

He considered that this fracture was of outstanding importance. In a series of 835 recent fractures of the lower end of the radius at Ancoats Hospital, 571 were Colles's fractures, 174 were separation of the radial epiphysis, and 90 were styloid and marginal fractures. Mr. Platt gave an account of the early papers and monographs on Colles's fracture, and proceeded to discuss the question of impaction. Stevens, of Boston, had recently put forward the view that the fracture was a true compression injury in which there was a crumpling of the posterior cortical surface, without any actual telescoping of the fragments. The fracture was common at all ages and in both sexes. It was commonly due to a fall on the outstretched hand. The line of fracture was transverse and lay within an inch of the articular surface of the radius, at a site where the bone was ill-fitted to resist a cross-breaking strain. Some displacement was present in not less than 75 per cent. of cases, but gross displacement—that is, the dinner-fork deformity—was relatively uncommon. The displacement might be only a backward tilt, with no displacement en masse, or the fracture might be comminuted. Involvement of the radio-ulnar joint, without alteration of its alignment, was not significant, but fracture of the ulnar styloid, or detachment of the triangular fibrocartilage, might interfere with the recovery of the function of rotation. In diagnosis, the loss of the normal anterior concavity of the wrist was the measure of the backward tilt; this was the important point to determine by inspection, palpation, and radiography. For anæsthesia, two satisfactory methods were available—viz., nitrous oxide anæsthesia, and local anæsthesia by injection of 20 per cent. novocain. The ideal conditions for local anæsthesia were a fracture of some hours' duration, presenting a hæmatoma on the dorsum of the wrist, into which the novocain could be easily and rapidly diffused through a single puncture.

The method of reduction he advocated was a combination of traction with direct force. The traction with hyperextension of the wrist disengaged the fragments. Direct pressure was then exerted on the fragments. Finally, traction combined with palmar flexion and adduction was used to overcome the radial deviation. The reduction was complete only when the lower articular surface of the radius looked downwards and forwards. The position for fixation was one of slight palmar flexion with the hand slightly adducted. The correct splint controlled the extensor surface of the forearm and hand as far as the metacarpo-phalangeal joints. Splinting of the flexor surface was of subsidiary importance. He advocated gutter splints of light metal, or moulded plaster-of-Paris splints.

Fractures without displacement could be treated by a short period of fixation and early mobilisation of the wrist, and of the inferior radio-ulnar joints. Five weeks were ordinarily required for firm consolidation, and the backward tilt might reappear during the first three weeks. After a prolonged trial of the method of treatment by early massage, he had decided that the main disadvantages of the method were the time and energy consumed, and the danger of recurrence of the deformity during massage, in spite of the most careful supervision of the massage students. He now advised a period of fixation lasting five weeks, with active use of the limb in the splint, but no removal of the splint for physico-therapeutic treatment. Certain patients were referred to the massage department at the end of the five weeks. Out of 111 cases treated at Ancoats Hospital during 1925 to 1928, only 3 showed bad results; 92 showed excellent and perfect results, the remainder (16) being classified as good, but not perfect.

Sir WILLIAM WHEELER (Dublin) said that Colles's work was all the more notable because his descriptions were based entirely on clinical observations. He never saw a dissection of a Colles's fracture. The method of applying tight-fitting plaster splints directly to the limb, as taught by Böhler, of Vienna, should be advocated with some caution. He had seen the loss of an arm and of a leg by the use of this method. The students in Dublin had heard so much of the method that one student, shown an X ray of a fractured skull, suggested treatment of the case in a bowler hat. Sir William suggested that slight deformity of the wrist might be consistent with a good ultimate functional result.

Mr. W. A. **Cochrane** (Edinburgh) said that one of the most important points to remember throughout the treatment of these fractures was that the radius was the hand bone. The apparent forward displacement of the ulna seen in some cases after treatment was the outcome of a failure to reduce the backward rock of the radius. There was a rotation displacement of the lower radial fragment on the upper, which could best be reduced by pressing on the ulna, as described by Cotton, and using it as a fixed point round which the lower radial fragment was wound.

Mr. Cochrane emphasised the importance of the hæmatoma in the fracture, and suggested that injection of a local anæsthetic into this hæmatoma might conceivably interfere with bone regeneration. This possibly accounted for the fact that at clinics using local anæsthesia as a routine considerably longer times were allowed for firm union of fractures, and consequently for immobilisation, as compared with those using general anæsthesia. Safety in splinting, he said, was of the utmost importance. Skin-tight plasters should be applied only by specialists; they were very dangerous in inexperienced hands.

Mr. H. A. T. **Fairbank** (London) said that he had found slight degrees of lateral displacement difficult—in some cases impossible—to overcome. Of all the displacements, the backward tilt was the most important to remedy. The type of splint did not matter. He, personally, found Carr's splint, with a wedge-shaped felt pad lying in front of the lower fragment, satisfactory. He reserved plaster splints for the difficult cases with late reduction and comminution. Massage and early mobilisation were used for fractures in old women. He thought stiff fingers were the worst problem met with in these fractures.

Mr. **Whitchurch Howell** (London) stressed the dangers of plaster-of-Paris splints, and the dangers, when using nitrous oxide anæsthesia, of the recurrence of deformity after reduction caused by sudden movements of the patient. He advocated fixation in supination. Stiff shoulders after Colles's fracture were due to injury to the shoulder at the time of the fracture.

Mr. G. E. **Wilson** (Toronto) said that one of the most useful ways to look on Colles's fracture was as a shortening of the posterior surface of the radius. He thought the cases of recurrence of backward deformity after reduction were more apparent than real. The swelling of the soft parts masked a poor reduction, which became obvious about the second week when the swelling had disappeared. He tested for full reduction by palmar flexion. If this was possible to a right angle, reduction was complete. He reduced fractures under the fluoroscope, and fixed the fracture in a plaster splint in adduction for two and a half weeks.

Mr. **George Perkins** (London) said he taught students to test for deformity of the anterior curve of the radius by palpation of the radial artery at the wrist, as in feeling the pulse. He also taught them to use anæsthesia in every case requiring reduction. The shortening of the radius led to lack of alignment at the radio-ulna joint. For this he advocated Baldwin's operation in severe cases.

Mr. F. **Crooks** (Nottingham) said he had been taught as a student to use posterior splints; he advocated brachial plexus anæsthesia for reduction, and deprecated too early removal of splints.

The **President** said that certain principles were taught to masseurs, namely: (1) Colles's fracture is not united in a fortnight; (2) it is possible to redisplace the fracture by early massage; (3) that the masseur should act mainly as a stimulus to the patient, to encourage use of the limb. He liked the plaster slab splint, and thought its correct use should be taught to every student.

Mr. **Platt**, in reply, agreed with Mr. Perkins that gross disalignment of the inferior radio-ulnar joint was a serious disability. In reply to Mr. Wilson, he said that he reduced his fractures by palpation, and checked the result by radiography. He did not use the fluoroscope. The stiff fingers, referred to by Mr. Fairbank and others, he thought were not due to ischæmic paralysis, but were neurotrophic in origin, possibly being caused by an irritation of the posterior interosseous nerve at the back of the fracture.

SECTION OF PATHOLOGY

With Prof. J. **Walker Hall** (Bristol) in the chair, a discussion on

Cholesterol Metabolism in Disease

was opened by Mr. J. A. **Gardner**, F.I.C. (London). Cholesterol, he said, was a constituent of all animal cells and body fluids; in health the urine contained mere traces, but in nephrosis there was considerably more. Cholesterol existed in two forms in the body, (1) free, (2) combined with the higher fatty acids as esters; and these forms were not equally distributed. The pathologist was interested in cholesterol because of the variations of the amount in the blood in disease; thus there was hypercholesterolæmia in some forms of nephritis, some cases of cholelithiasis, of diabetes, &c. Physiological increase of blood cholesterol also occurred, for example in pregnancy. Secondly, pathologists were concerned with the deposits of cholesterol or of cholesterol esters in the tissues, for example, those in the normal suprarenal cortex, in atheromatous intima, in inflamed kidney, and in other organs. Cholesterol inhibited the hæmolytic action of saponins. By prolonged feeding, cholesterol infiltration of tissues could be produced in rabbits, and changes were produced which had been believed to resemble pathological processes in man.

During the past 20 years chemical had been acquired more rapidly than physiological knowledge. Due mainly to the brilliant work of A. Windaus and H. Wieland, it had been shown that there was an intimate chemical relationship between cholesterol and the bile-acids, and tentative structural formulæ had been assigned to cholesterol, to the bile-acids, and to their products. Mr. Gardner gave the following scheme to illustrate the relationships between the different substances:—

(Parent hydrocarbon)	Cholestane		Coprostane
	↓		↓
(Unsaturated alcohol)	Cholesterol	⇄	Allocholesterol
	↓		↓
(Saturated alcohol)	β-cholestanol		Coprosterol
	↓		↓
(Bile-acid)	Hyodioxycholic acid		Cholanic acid and hydroxy derivatives.

In vertebrate animals the only unsaturated alcohol isolated from tissues was common cholesterol; recently it had been shown that this was generally accompanied by 1 to 5 per cent. of β-cholestanol. From the bile of different animals, on the other hand, many different bile-acids had been isolated, and when similar bile-acids were found in two species their proportions might be very different; consequently the results of animal experiments were not necessarily applicable to man.

There was little or no precise information, Mr. Gardner said, as to the functions of cholesterol in the body. In man, analyses had been made of the blood, of the excreta, and of tissues obtained post mortem. Before attempting to assess the meaning of the results of such analyses in disease, it was necessary to review the origin and fate of cholesterol in the body. From their own work and that of others up to that time Dr. Dorée and himself had some years ago formulated the following working hypothesis :—

1. Cholesterol is a constant constituent of all cells, and when these cells are broken down the cholesterol is not excreted, but is used in the formation of new cells.
2. The liver breaks down dead cells—e.g., blood corpuscles —and eliminates their cholesterol in the bile.
3. The cholesterol is reabsorbed from the intestine, probably as esters, together with bile-salts, and is carried in the blood for reincorporation in new cells. The destruction of red corpuscles is now attributed to the reticulo-endothelial system in general.

It had been shown by experiments on dogs that cholesterol was readily absorbed from the intestine and transported in the chyle. Bile-acids had the property of uniting with substances insoluble in water—e.g., fats, fatty acids, cholesterol—to yield compounds whose salts were soluble in water—the "choleic acid principle" of Wieland—thus affording an explanation of the transport of such substances through the intestinal wall. It had been shown that cholesterol could be synthesised in the body, but the seat of such synthesis had not been clearly established. In the adult more sterols were excreted in the fæces than were taken in with the food. Further, it was clear from observations on isolated portions of human intestine that sterols could be excreted into the bowel as well as in the bile. The main sterol of adult fæces was coprosterol, which was believed to be produced from cholesterol by reduction due to the action of bacteria. In milk-fed infants the fæces contained cholesterol, but not coprosterol; the stage at which the reduction to coprosterol started was not known. The influence of feeding animals with cholesterol, or cholesterol-rich diets, varied in different animals as regards the possibility of producing aortic changes. The experiments were most successful in rabbits, much less in rats and mice, and negative in dogs and cats. Mr. Gardner concluded that in man there was no real evidence pointing to any connexion between atherosclerosis and exogenous cholesterol metabolism.

BLOOD CHOLESTEROL

In about 50 healthy individuals of both sexes the total cholesterol of the fasting plasma varied from 0·08 to 0·23 per cent., of which from 60 to 70 per cent. was in the form of esters. There was no such thing as alimentary hypercholesterolæmia *after a meal*; the plasma cholesterol sometimes rose and sometimes fell during the hours succeeding the meal. At the same time prolonged feeding with diets of high cholesterol content eventually raised, and of low cholesterol content eventually lowered, the pre-breakfast level of the plasma cholesterol. Some cases of pregnancy showed an increase of the total cholesterol, and many more exhibited variations in the ratio of free to ester cholesterol.

In uncomplicated cholelithiasis without jaundice there was no hypercholesterolæmia, and the ratio of free to ester cholesterol was normal. With biliary obstruction there was generally a fall in the ester cholesterol; the same picture was found in subjects with biliary fistulæ; it looked therefore as though the absence of bile from the intestine in both groups reduced the absorption of sterols, and so lowered the ester cholesterol content of the plasma. In a minority of cases with cholelithiasis and obstructive jaundice there was hypercholesterolæmia, with an increase of both free and ester cholesterol; the explanation of this was not clear. The hypercholesterolæmia of nephrosis might reach as much as 1 per cent. total cholesterol, and the ratio of free to ester cholesterol varied in either direction. Its cause was not known, but it might be related to the disturbance of the plasma proteins. The total cholesterol of the plasma might also be raised in myxœdema. In both myxœdema and nephrosis the basal metabolic rate was lowered, but it was not fair to regard the blood cholesterol as inversely proportional to the basal metabolic rate, because in hyperthyroidism the increased rate was accompanied by a normal plasma cholesterol.

Mr. Gardner concluded by referring briefly to the histological study of pathological deposits of cholesterol esters in tissues, as in chronic nephritis, Niemann's disease, atherosclerosis, and xanthoma. Some of these deposits were attributed to hypercholesterolæmia, but others were not associated with an increase of the blood cholesterol. Conversely, the hypercholesterolæmia of nephrosis did not lead to xanthomatous deposits.

EXPERIENCE IN FREIBURG

Prof. **Ludwig Aschoff** spoke particularly of vascular disease. The anisotropic droplets in the intima of pathological vessels definitely contained cholesterol esters. In atheroma of the aorta fats, phosphatides and cholesterol compounds were all in excess; but the last group of compounds were in greatest excess; the other two groups were not of much importance. The deposition of lipoids occurred first at the boundary between intima and media, probably in the cementing substance between the elastic fibres. The deposits then increased and spread towards the lumen of the vessel. Deposits in the media occurred later, and started at those points where the elastic fibres were loosely knit. It used to be thought that the changes were essentially intracellular, but nowadays atheroma was regarded as an imbibition process, the lipoids being derived from the blood plasma.

Changes in the vessels began in early childhood. The special pictures observed at different stages were due to the superimposition of special circumstances at the different stages of life. Thus in early life the picture was one of simple imbibition of lipoids. In later life there was in addition a reactive hyperplasia of the intima. Such factors as wear and tear, necrosis, and calcification were also added with increase of years. It was tempting to speculate on the main influences at different ages. Thus might the high cholesterol content of milk be responsible for vascular changes observed in babies? Was the atheroma of puberty due to a disturbance of the ductless glands? Was the atheroma of adults due to dietetic influences, possibly superimposed on changes produced as suggested at earlier ages? Special cases might be affected by special additional factors—e.g., the hypercholesterolæmia of diabetes. Particular caution was necessary in interpreting the results of feeding rabbits with cholesterol when attempting to explain pathological changes in the vessels of man. He favoured the view that atherosclerosis in man was a form of "cholesterol gout," a metabolic disease not necessarily due to any gross changes in the chemical composition the blood. Finally, Prof. Aschoff reminded his eners of the great importance of mechanical factors .g., the blood pressure, the effect of stretch and ss, the influence of weak spots in the walls, of ves, and the strain at points of branching, &c.—determining the localisation of atheroma.

)r. R. SCHOENHEIMER pointed out that cholesterol osition in the tissues of normal man by prolonged ding with cholesterol was impossible, owing to the ans available for its ready excretion. Such position might occur, however, if excretion of sterols s restricted. He presented most interesting experi-ntal results of a comparison between the sterol ntents of normal intestine and of isolated loops of t. Cholesterol was excreted into the normal bowel; me of this was reabsorbed; some was converted to coprosterol and β-cholestanol, neither of which uld be reabsorbed. In the isolated loop much cholestanol but little cholesterol was found. He d been able to extend his investigations to a case xanthomatosis of the tendon sheaths in man. The itial hypercholesterolæmia (some 850 mg. per 0 c.cm.) was due mostly to the ester form; it was duced to about 300 mg., with a normal free to ester tio, by a purely vegetable diet (which contained ly plant sterols, which were not absorbed). He was t able to say where the cholesterol of the blood had one; it was certainly not excreted. This patient had creted very little sterol even on a full diet; it was robable that her hypercholesterolæmia was due to diminished fæcal excretion; it was worth while xamining other cases of hypercholesterolæmia for npaired excretion, and when that was found adopting reatment by a vegetable régime. He regarded these ases of cholesterol deposition as analogous to gout, n that the abnormal metabolism was due to a failure f excretion.

DISCUSSION

Dr. S. C. DYKE (Wolverhampton) discussed lipoid splenomegaly, which he regarded as due to a saturation of the reticulo-endothelial cells with lipoids. This might be due to a failure of excretion, or be congenital. He described the three main groups, Gaucher's disease, in which cerebrosides (kerasin or phrenasin), Niemann-Pick's disease, in which phosphatides (especially lecithin), and the Schüller-Christian syndrome, in which cholesterol was found in the deposits. He regarded all these as congenital in origin, and contrasted them with acquired lipoid splenomegaly, such as that due to the hypercholesterolæmia of diabetes or biliary obstruction.

Dr. J. W. MCNEE (London) dealt with some of the aspects of biliary disease, and pointed out in particular how greatly our knowledge of these diseases was held up by lack of a simple method for estimating bile-acids.

Dr. H. GAINSBOROUGH summarised the main causes of hypercholesterolæmia. Dr. J. M. H. CAMPBELL dealt with some clinical aspects of cholelithiasis and atherosclerosis, and Dr. J. D. ROBERTSON read a paper for Prof. E. C. DODDS, in which it was pointed out that in nephrosis the hypercholesterolæmia did not run strictly parallel with the degree of œdema. Further, it had been observed in cases of ascites, that though the plasma proteins fell after tapping the abdomen, the blood cholesterol did not rise.

Prof. ASCHOFF answered points which had been raised, and Dr. SCHOENHEIMER recounted a case of nephrosis in which marked atherosclerosis was found, thus negativing the general belief that intimal changes did not occur in this disease. Further points were discussed by Prof. M. J. STEWART, Dr. CECILIA SHISKIN, Dr. W. W. KAY, and Dr. DAM (Copenhagen)

REVIEWS AND NOTICES OF BOOKS

uantitative Clinical Chemistry

Vol. II. *Methods*. By JOHN P. PETERS, M.D., M.A., Professor of Internal Medicine, Yale University School of Medicine; and DONALD D. VAN SLYKE, Ph.D., Sc.D., Member of the Rockefeller Institute for Medical Research. London: Baillière, Tindall and Cox. 1932. Pp. 957. 52*s*. 6*d*.

THE first volume of this work showed that one of the most ambitious attempts of recent years was likely to be successful. To summarise quantitative clinical chemistry in two volumes is an achievement indeed. Since one of the authors, Dr. Donald van Slyke, has succeeded during the past 20 odd years in making a quantitative series of biochemical methods out of what had hitherto only possessed the merest shadow of mathematical exactitude, no better collaborator on the biochemical side could have been chosen. Indeed the whole development of the manometric technique for the measurement of the concentration of the ordinary constituents of blood and urine has been achieved almost solely in the laboratories of the Rockefeller Institute.

The first chapter containing some 50 pages deals with the general methods employed in quantitative biochemical analyses. It might seem superfluous in a volume of this character to start with a description of balances, measuring flasks, and burettes; but so much information is compressed in a short space that there can be little doubt that it was worth while. One of the most interesting parts of this chapter deals with the importance of accurate calibration of volumetric apparatus. It is pointed out that the accuracy of graduation necessary for ordinary work is plus or minus 0·1 per cent., and moreover that liquids different in specific gravity and surface tension cannot be delivered with the same accuracy by a pipette graduated in terms of water. Whilst this fact is self-evident, its emphasis is of the utmost value. A very good description of micro-volumetric apparatus and a particularly useful account of the Rehburg burette and the use of this instrument in micro-titration is supplied. The preparation of standard solutions is also discussed and exact directions are given for the preparation of standard hydrochloric acid, while the principles of colorimetry and nephelometry are outlined.

The second chapter is concerned with special biochemical methods and deals with the collection of samples. The technique of arterial puncture, the collection of arterialised venous blood, and venous puncture are well described. A valuable part of this chapter deals with the anaerobic handling of blood; this is very complete and will enable the investigator to collect blood anaerobically and centrifuge it. The third chapter deals admirably with gas analysis, including the newer methods of analysis by the manometric van Slyke apparatus. There follows a series of chapters on respiratory metabolism, alveolar air, and blood volume. The remaining chapters concern the determination of the constituents of blood, urine, and fæces, and wherever possible a colorimetric, manometric, and volumetric method has been given. The methods described have been selected with the greatest discrimination and criticism of the judgment of such authors would seem almost impertinent. We make a few plaintive suggestions in the hope that in future editions the authors will lighten our darkness on certain problems which they have not touched. For example, the determination of iodine in blood or other body fluids and tissues is not discussed—a subject of great importance which has attracted world-wide interest during the past few years. Nor is there any mention of enzymes. The determination of diastase and phosphatase are matters which occupy a good deal of the time of the biological chemist associated with clinical routine work. We should welcome the opinions of Dr. Peters and Dr. van Slyke on the relative values of a multiplicity of methods.

Any clinician or clinical biochemist who intends to publish a book or a paper should first consult this volume in order to see whether he can really advance the subject beyond the point to which the authors have already taken it. The volume will remain a permanent monument to the workers at the Rockefeller Institute.

Die konservative Behandlung entzündlicher Genitalerkrankungen der Frau

By Priv.-Doz. Dr. GUSTAV DÖDERLEIN. Leipzig: Georg Thieme. 1932. Pp. 117. M.6.50.

THIS small volume is one of an excellent series which is distinguished by the attention paid to treatment. The conservative treatment of inflammatory lesions of the female genitalia affords ample scope for the keen therapist, and extremely good results are often obtained. Practitioners should derive great help from a study of this book, for they will find most of the available methods adequately described. Particularly useful are the sections dealing with vulvitis, pruritus vulvæ, and gonorrhœa. The paragraphs in small print deserve careful study, for they indicate clearly the modern views on the pathology of the lesions. The younger Döderlein, ho has written this book, is now Oberarzt under of. G. A. Wagner at the Charité, Berlin. He seems have inherited the ability to record concisely the clinical experience of the German school.

Constitution-Types in Delinquency

By W. A. WILLEMSE, M.A., Dr.Phil., Lecturer in Psychology, University of Pretoria. London: Kegan Paul, Trench, Trübner and Co., Ltd. 1932. Pp. 266. 15s.

THE work of Kretschmer has opened up a new field for work in psychiatry. Hitherto it might be said that apart from the established organic psychoses such as general paresis, alcoholic psychosis, post-encephalitic delinquency, and senile dementia, little has been done to correlate the reaction types with the physical peculiarities of the patients. True, Lombroso and his followers had marked off the alleged stigmata of degeneration, but constitution manifest in physique had never been closely studied before Kretschmer had suggested that pyknic, asthenic, and athletic physiques were correlated with manic-depression, schizophrenia, and epilepsy respectively. Many psychiatrists have found this correlation useful, and physiological undercurrents have been speculated upon to explain the emergence of these reaction types on the basis of endocrine polarities. But most maintain a receptive critical attitude without committing themselves to the dangers of water-tight compartments. Dr. Willemse has ventured to extend the Kretschmer classification to the study of criminal types. He does so with a wealth of clinical material but with an equal poverty of statistical verification. His descriptions of physical types are clear and suggestive, and his descriptions of the mental make-up of cycloid, schizoid, and epileptoid subjects is entertaining and instructive. But the descriptive clinical material based upon fairly ill-defined mental characters is difficult to correlate against equally descriptive types of physique. He does not, however, neglect intermediate forms nor the importance of dysplasia for delinquency, and his references are rich and well considered. The subject is still in the descriptive stage, but because of its novelty and suggestiveness, and for the bridge it builds between the physical and the mental, the book is welcome, and deserves to be studied for its own sake and to stimulate further research.

Human Pathology

Third edition. By HOWARD T. KARSNER, M.D., Professor of Pathology, Western Reserve University, Cleveland, Ohio. London: J. B. Lippincott Company. 1932. Pp. 1012. 45s.

IN its third edition this useful text-book has been carefully revised and new sections have been added on œdema, shock, rheumatic fever, and diseases of the teeth; the last is from the pen of Prof. Thomas J. Hill and forms a welcome addition to a pathological text-book. The sections on Bright's disease and endocarditis have been very largely rewritten in accordance with recent teaching. A useful feature is the list of references appended to each chapter; some older references have now been removed and 600 new ones have been added. We are glad to note that the author has resisted any temptation to enlarge the book; this edition contains only some 30 pages more than the last, and the volume as a whole is still one of the most compact, yet complete, text-books available.

British Journal of Children's Diseases

IN the July–September number (vol. xxix.) Dr. D. D. Payne records observations on 274 children who attended the Royal Waterloo Hospital Rheumatism Supervisory Centre between January, 1931, and March, 1932, giving statistics of familial incidence, social environment, relation to tonsillitis, chorea, and carditis, followed by an account of the methods of diagnosis and treatment carried out by his centre and details of a cardiac efficiency test.—In a paper on the Erythrocyte Sedimentation Rate in Juvenile Rheumatism, Dr. N. Gray Hill describes his method which is a modification of that of Fahraeus, with an account of eight illustrative cases. He holds that if the rate is below 10 : 20, active rheumatism other than chorea is not present and there is no real necessity for hospital treatment, whereas if the readings are above 10 : 20 the indications for rest in bed and more careful observation are increased.—Dr. Edward Podolsky, of Brooklyn, New York, contributes a paper on Calcium Therapy in Pædiatrics, and Dr. Norman D. Begg records a Ward Outbreak of Erythema Nodosum, which occurred in a ward containing 12 children, all under 6 years of age, convalescent from whooping-cough. In each case the Mantoux reaction was strongly positive, and X ray examination of the chest showed a slight increase in the root shadows, suggesting some degree of hilar gland infection.—Dr. Hazel H. Chodak Gregory describes Two Cases of Melæna Caused by Innocent Growths of the Small Intestine in girls aged 5 and 8 years respectively. In both cases the intestinal hæmorrhage gave rise to severe secondary anæmia. Recovery followed removal of the growths in each case.—Prof. Amir Chand, of Amritsar, reports a Case of Mongolism in India, which is apparently the first on record.—The abstracts from current literature are devoted to dermatology and syphilis.

Vitamin D. IS PRESENT IN ALL

CADBURYS
CHOCOLATES

1 Cadbury Bros. wish to inform doctors that, as a result of tests carried out for them by a high authority, it has been shown that the cacao bean contains Vitamin D. (one unit of anti-rachitic activity per gram).

2 The methods of manufacture of Cadbury's chocolates result in the retention of the Vitamin D. natural to the cacao bean.

2 VACCINES OF PROVED ACTIVITY

Reminders and Suggestions

ACECOLINE

Pure stabilised Acetylcholine Hydrochloride for the treatment of Arteritis, Raynaud's Syndrome, Arterial Spasms, etc.

Boxes of 6 Ampoules in doses of 2, 5, 10 & 20 ctgs.

ADREPATINE

A combination of Pluriglandular and Vegetable Extracts with Stovaine for the rational treatment of Hæmorrhoids.

Ointment: Tube with Canula—Suppositories: Box of 16.

BIVATOL

A Lipo-Soluble Bismuth which is practically equal in effect to the Arsphenamine Compounds in the treatment of Syphilis, Yaws, etc.

Boxes 12 Ampoules of 2 c.c.

EMGE (LUMIERE)

Pure Magnesium Hyposulphite for the treatment of Alimentary Anaphylaxis, Migraine and all Allergic Conditions.

Tablets: Packages of 40. Ampoules, 10 c.c., boxes of 3.

HYPOTENSYL

The active principles of Viscum (Gui) with Hepatic and Pancreatic Extracts for the treatment of conditions associated with High Blood Pressure.

Bottles of 50 Tablets.

MYCOLACTINE

A combination of Bile Extract, Yeast, and Lactic Ferments for the rational treatment of Alimentary Toxæmias, Intestinal Stasis and Constipation.

Bottles of 50, 500 and 1000 Tablets.

Literature and Samples on request from

THE ANGLO-FRENCH DRUG CO., Ltd.,
11 & 12, Guilford Street, LONDON, W.C.1.

INFECTION WITH BRUCELLA ABORTUS

IT is now becoming fairly clear that man may become infected with *Brucella abortus* from two main sources—milk and direct contact with animals. Since, according to the most recent observations, 20–40 per cent. of the mixed milk-supplies in towns not practising pasteurisation contain living *abortus* bacilli, and since a high proportion of our herds of cattle are infected, the question is often asked why undulant fever is not more common in this country than it appears to be. Even admitting that only a fraction of the cases are correctly diagnosed, and that the number of reported cases affords but a poor index of the true incidence of the disease, there is still a serious discrepancy between the frequency with which human beings are exposed to infection and the frequency with which they develop clinical symptoms of infection. The answer seems to be that infection with *Br. abortus* resembles in many respects infection with the tubercle bacillus. We know that 6·4 per cent. of the mixed milks of this country contain living tubercle bacilli of the bovine type, and we know that only a small proportion of those consuming this milk develop clinical tuberculosis. The evidence of the tuberculin test, however, shows that latent infections, either with the bovine or the human type of bacillus, are extremely common. Most of these latent infections give rise to little or no trouble, and only a small proportion of them progress to the stage of becoming clinically manifest.

If the analogy with tuberculosis is correct, latent infections with *Br. abortus* should likewise be common, and this, in fact, appears to be so. The evidence obtained by examining Wassermann sera indicates that latent infection resulting from the ingestion of raw milk may often be encountered, especially in the first 20 years of life. With regard to infections by direct contact, the evidence is even more conclusive. A. THOMSEN,[1] in Denmark, found that veterinary surgeons working with infected cattle frequently had antibodies to *Br. abortus* in the absence of any history of undulant fever. Prof. J. H. DIBLE and Dr. MARGARET POWNALL[2] at Liverpool have now brought evidence to show that much the same holds true of men engaged in slaughtering animals and dressing meat. Of 100 slaughterers examined, 12 had an agglutination titre of 1/40 or over to *Br. abortus*, while of 100 control males of the same age-groups only 2 reacted at this titre. Particularly interesting was their observation that antibodies were absent from those men engaged in slaughtering pigs, but were present in those dealing with cattle and to a rather less extent with sheep. In view of the fact that contagious abortion has never been observed in pigs in this country, the negative results in pig-slaughterers lend additional weight to the thesis that antibodies in the blood to a titre of 1/20 or 1/40 are the result of actual infection with *Br. abortus*. The positive results in a number of slaughterers of sheep suggest that these animals may be infected with an organism of the brucella group, and they clearly demand further investigation.

While those in actual contact with animals may perhaps be infected through the skin, it is usually assumed that townspeople and milk-drinkers generally are infected through the alimentary tract. The theory is that when the bacilli are ingested in milk or cream, they are swallowed, pass through the stomach, and are apt to find their way through the wall of the intestine and so reach the mesenteric glands. Another route, however, is possible—namely, through the tonsil. In support of this C. M. CARPENTER and RUTH A. BOAK[3] at Rochester, New York, have recently adduced some interesting evidence. Fifty-six pairs of tonsils removed from children and adults for various causes were examined culturally and by guinea-pig inoculation, and in eight of them *Br. abortus* was demonstrated. Except for one patient who lived on a dairy farm and about whom exact information was unobtainable, all the positive cases had drunk raw milk known to contain *Br. abortus*, though only one patient was actually suffering from undulant fever at the time. CARPENTER and BOAK suggest that the organism may invade the tonsil and multiply or accumulate there until the resistance of the host is sufficiently lowered by fatigue or disease to permit of its invading the blood stream. How common primary invasion of the body via the tonsil may be it is impossible to say; it will be remembered that this route of entry has also been claimed for the typhoid bacillus, though the balance of evidence—especially that obtained from the experimental study of mouse typhoid—is against it. Before coming to any decision it would be necessary to make a comparative examination of the tonsils and mesenteric glands of raw-milk drinkers coming to autopsy. Some large hospital in a provincial town in which pasteurisation is exceptional might well make this a subject of inquiry.

◆

MORAL AND MATERIAL PROGRESS

THE British Association for the Advancement of Science was born in York 101 years ago. Its objects were "to make the cultivators of science acquainted with each other, to stimulate one another to new exertions, to bring the objects of science more before the public eye, and to take measures for advancing its interests and accelerating its progress"—an admirable summary of the ideals which have, with so much benefit, led to the founding of the innumerable learned societies which have arisen during the century. We doubt whether medical men affect the meetings of the Association as much as they might. They have at any rate the advantage that doctors can there meet many interesting people with whom they would be unlikely to come into contact elsewhere and that there is no section of medicine or pathology or hygiene, nothing indeed of a more professional complexion than the section of physiology, and even this was omitted this year in view of the international gathering at Rome. The doctors therefore are free from obligations and can wander at will to papers and discussions on archæology or zoology or economics or what not for edification rather than instruction; they will also find well-organised facilities for entertaining excursions.

[2] Jour. Hygiene, 1932, xxxii., 349.

[3] Jour. Amer. Med. Assoc., July 23rd, p. 296.

The present meeting at York—the fifth to be held in that splendid city—opened on August 31st with the presidential address by Sir ALFRED EWING, the veteran leader of scientific engineering, and though he made no direct reference to our immediate interests his words are worth some consideration by those who care to reflect on the broader aspects of medical practice. As might be expected, he celebrates particularly the sweeping pageant of discovery and invention which he has watched go by in his own experience and which has led man to a control of his material environment no one could have dreamed of when the President attended his first meeting of the Association 65 years ago. The miraculous has progressively become the commonplace, human life thereby has become richer, fuller, wider, healthier, and time and space have been so far abolished that the whole world is now in closer contact than Edinburgh was with Inverness 100 years ago. The pageant must needs have moved the wonder and admiration and delight of anyone who had eyes to see it. But Sir ALFRED goes on to two comments which really contain the pith of his address. Uncertainty, he says, is now replacing the cocksureness of the Victorian spokesmen of science who used to think that there was somewhere a finite explanation of the world to which the progress of knowledge would inevitably lead. This quest of truth has gone on ceaselessly and it has brought us now to doubt whether there is any truth to find more final than the steps which open up fresh questions. We discover new relations between observed phenomena, but the nature of what is found to be related continues to evade our comprehension. Relationships are apparently the only kind of discovery which we can make; we see more clearly where the procession is and it becomes more inclusive, but we do not now know where it is going to. The nature of things becomes more and more incomprehensible, and the procession becomes more and more absorbingly interesting by our very realisation that it can never reach a goal. And to a stimulating statement of this great truth Sir ALFRED adds some rather gloomy reflections. Admiration is, he says, now tempered with criticism, complacency gives way to doubt, doubt passes into alarm. Where are we going to? The engineer has showered over the earth an unimagined wealth of capacities and powers which has made for such happiness as material things may secure. But his gifts may be abused and the President goes so far as to say that ethically and morally man is not fit for the responsibilities which his material progress involves.

While it is true that man is never morally fit we venture to think that Sir ALFRED underestimates the ethical progress which has been made since the British Association was founded, and that if he had had more contact with biology he would not be so pessimistic about man's capacity to meet effectively any situation which may arise. He has been used to machines which need outside intervention if their hurts are to be healed, which work only under limited conditions and which have no power to adapt themselves to their surroundings. The tale which biology tells is far more cheerful; we see everywhere self-regulating adaptable organisms which evade and surmount their difficulties and fit themselves to what they find about them. The great lesson of the postmortem room is not that man often fails to carry on his life, but that the body faces overwhelming troubles with a cheerful courage which keeps many an active spirit alive for years in a carcass which is irretrievably maimed. The biologist will have few qualms about man's suitability to play his part in a world which he has himself transformed. Sir DANIEL HALL has watched the same pageant as Sir ALFRED EWING but from the agriculturalist's standpoint: "righteousness," he says in a striking essay,[1] "is just as much a quality of the human mind as intelligence. Both are fitful in their operations, irregular in their distribution, and unequal in their intensity. I hold that both are growing in the human race from generation to generation, and this again I maintain to be a fact of observation, dependent on no assumptions of how or why." The fearful may well take fresh courage.

THORACOPLASTY IN PULMONARY TUBERCULOSIS

THE most important part in the treatment of chronic pulmonary tuberculosis is the treatment of cavities. There is always hope for the tuberculous lung which is free from these incubators which might have been designed by nature for the breeding of tubercle bacilli. The closure of a cavity means much more than the closing of an ugly gap in an essential organ; it implies a substantial reduction of the attacking forces. By the time that the lungs are the seat of chronic tuberculous disease the period of hæmatogenous infection has probably passed and we can aim at local victory with some hope of permanent cure. The types of cavity associated with early infiltration often heal spontaneously if the patient by taking to his bed relieves the lungs of the extra work necessary for active life. Cavities of a slightly more resistant type will often yield to pneumothorax treatment. Basal cavities may close as the result of a timely phrenic avulsion. Such closure of cavities results in amelioration of symptoms, reduction of expectoration, the disappearance of tubercle bacilli, and the healing of diseased tissues. These beneficent results, however, are only possible if the pleura is free from adhesions of the type which, either because of their situation or size, prevent adequate collapse of the lung and maintain the patency of cavities.

---

[1] Fortnightly Review, December, 1931.

The division of adhesions which are preventing a satisfactory collapse of the lung may convert an inefficient into an efficient pneumothorax. Much progress has been made since JACOBAEUS devised his endoscope for the direct inspection of the pleural cavity and a cautery for severing adhesions. The employment of a high-frequency current to coagulate tissues before cutting with actual cautery or diathermic knife has lessened the danger of hæmorrhage and some at least of the difficulties formerly encountered in this very delicate operation have been obviated. But the division of adhesions is often impracticable either because of their situation, or because they contain pulmonary tissue, or because the lung itself is adherent to the chest wall. When internal pneumolysis is impossible, external pneumolysis is the only alternative to an expectant policy that in many cases might almost be termed a policy of despair. But it should never be forgotten that the results of thoracoplasty are irrevocable, that the operative risks are grave, and that it often fails in its object. A valuable review by BÉRARD and DELGOFFE[1] describes how certain of these risks may be avoided and emphasises the necessity of careful collaboration between physician and surgeon at all stages of treatment. It would be unfair to condemn any method of treatment because it is not always successful, or to judge of results from a limited number of cases: no doubt many lives have been prolonged and some lives have been saved by thoracoplasty; but the physician who recommends the operation shoulders a heavy responsibility. Those whose candour compels them to report operative failures have been termed "crêpe-hangers." At the risk of joining that lugubrious company we must confess that the extremely favourable returns published from time to time by thoracic surgeons are less impressive than the results of operative interference seen not as statistical percentages but as tragic realities in the post-mortem room.

Though artificial pneumothorax is the best method of treatment for the varieties of tuberculosis which demand active intervention, it leads to permanent cure in only a proportion of the patients treated. The risks attaching to it are however small, the patient suffers no pain and little inconvenience, and at any stage in the course of treatment the lung can be permitted to re-expand. Thoracoplasty produces a less effective collapse than a successful artificial pneumothorax: the mental distress caused by an operation that usually necessitates two and sometimes more visits to the operating theatre must be severe; the physical suffering after operation is often acute; and a successful result can never be guaranteed. A distinguished American physician who visited Europe last summer explained that the object of his coming was to find out "why his thoracoplasties died." He added that neither in Berlin nor in London was any satisfactory reply forthcoming. Improvements in the technique of partial thoracoplasty and apicolysis may enable us to dispense with the more radical methods and reduce operative risks, but it does not seem likely that surgery tried, found wanting, and abandoned in the treatment of tuberculosis of bones and joints should prove more successful in the thorax than it has in the limbs and spine. It is distressing when a patient succumbs in spite of our efforts, but it is much more distressing when a patient dies because of our efforts. When disaster occurs the physician cannot blame the surgeon. It is the operation rather than the operator that has failed—an operation usually undertaken on the advice of the physician. Desperate diseases may demand desperate remedies, and when nature fails to cure we must perforce employ art. But a natural cure is always to be preferred to an artificial one, nor should we forget that for every patient saved by our crude therapy nature cures a thousand by means too subtle for our heavy understanding. It is for this reason that statistics so often fail to convince. We know that the majority of patients survive the operation of thoracoplasty. What we need to know is how many lives are saved by thoracoplasty which would otherwise have been lost. It is noteworthy that the type of disease considered most suitable for this operation, the proliferative type occurring in the post-adolescent years, is the type which tends to pursue a chronic course without special treatment and is subject to prolonged remissions. Despite the admiration which the persistence, skill, and courage of the small band of thoracic surgeons rightly evoke, the physician will serve neither the cause of medicine nor the interests of his patients unless he views their work with a critical eye.

◆

THE Secretary of State for Scotland has appointed Dr. James Law Brownlie to be chief medical officer of the Department of Health for Scotland in succession to the late Dr. John Parlane Kinloch. Dr. Brownlie, who graduated at Glasgow in 1913 and obtained the M.D. (with commendation) in 1918, is at present one of the medical officers of the department and has been engaged on the coördination of hospital services in Scotland. He has represented the department on various scientific bodies and committees, and throughout his period of service has worked in close association with the late Dr. Kinloch. His previous experience included posts as resident medical officer in the Glasgow corporation fever hospitals, as assistant bacteriologist in the Glasgow corporation laboratory, and as bacteriologist and pathologist to the county of Lanark.

ANNOTATIONS

HIGH MATERNAL MORTALITY

In the final report of the Departmental Committee of the Ministry of Health on Maternal Mortality and Morbidity, reviewed recently in our columns,[1] attention was drawn to certain areas of England and Wales in which the risks of childbirth have for many years been appreciably above the average for the whole country. The details of the investigations from which this information was supplied have now been published as a separate report (No. 68 in the Ministry of Health's series on public health and medical subjects).[2] The areas studied were certain industrial towns in the West Riding of Yorkshire, the county of Lancashire, and ten counties of Wales. It had been observed for many years that an exceptionally high maternal death-rate prevailed in these areas, and reference has been made to it previously in various official reports. It was considered, however, that a somewhat more detailed investigation was desirable to ascertain whether fresh light could be thrown upon the causes of maternal mortality, whether the maternity and child welfare organisation was adequate, and, if so, why it had apparently failed to secure an improvement in the maternal mortality-rate. The inquiry was directed by Dame Janet Campbell, M.D., who herself studied conditions in the Yorkshire towns. Dr. Isabella Cameron and Dr. Dilys Jones were responsible for the inquiries made in Lancashire and in Wales respectively.

In Yorkshire's industrial towns it was noted that the high death-rate was due mainly to "other causes" rather than to puerperal sepsis. This naturally suggests an exceptional incidence of difficult or abnormal midwifery cases. The death-rates for both stillbirths and neonatal deaths were also above the average, which indicates that the excess of abnormal midwifery arises from those causes which may injure the child besides increasing the maternal risk—e.g., toxæmia, hæmorrhage, difficult labour due to disproportion or any cause likely to lead to premature birth. The report is unable to lead us any nearer to an explanation of this excess. It existed under pre-war conditions of comparative plenty. It is still present in times of wider unemployment and poverty. It cannot, it is concluded, be wholly accounted for by any outstanding characteristic common to all the areas, or by any local custom such as the employment of married women in the mills. Dame Janet Campbell suggests that much of the difficult midwifery is caused by disproportion between the size of the pelvis and the head of the fœtus, but it is not easy to see why this factor should have so distinctly local a distribution. In fact, the localisation of the high maternal death-rate to certain districts in Lancashire leads Dr. Cameron to reject the explanation that there is involved a question of race and consequent small pelvic development. She concludes, from her examination of the causes of maternal death in the county, that rickets is not a factor of the first importance. As in the Yorkshire towns, there is no conclusive evidence that the employment of women in factories, either before or after marriage, has a direct effect on the loss of maternal life at childbirth. Although it is true that the general experience is that the rate tends to be high in the cotton textile towns, Lancashire towns with the highest maternal mortality-rates are not exclusively those in which women are employed to a large extent in factories, while some towns with relatively low rate have much industrial employmen of women. Most of the local authorities, it is shown have established well-considered schemes for matern welfare, but many of these, Dr. Cameron believe fail in their full effect because they are insufficientl utilised. In the Welsh counties considered b Dr. Dilys Jones, on the other hand, it is conclude speaking generally, that the facilities provided for th care of maternity cases are far from adequat Comparatively few authorities have establishe antenatal clinics or made other arrangements for th routine medical examination of expectant mother Even recognising the financial and geographic difficulties in rural areas, it is felt that more adequat provision could be made, though, here also, due advan tage is not taken by the mothers of those maternit services which are provided. Another factor con sidered by Dr. Jones is the use of forceps. Statistic derived from the birth inquiry cards of health visitor or from the registers of midwives suggest that forcep are applied with unnecessary frequency. It is almos impossible to secure reliable information on th incidence of abortions, but the impression is state that there is a considerable amount both in the rura and the industrial parts of Wales, and that the practic of procuring abortion is increasing, probably owing t economic conditions.

From this summary it is clear that no new o outstanding causes of maternal mortality have bee discovered. But the report places in their prope perspective many factors which have been held t contribute to a high maternal death-rate. Succes can only be obtained by simultaneous progress i several different directions. Among these, in Dam Janet Campbell's opinion, must be included (1) th creation of a better informed public opinion in matter relating to maternal welfare ; (2) the maintenance o a healthy environment through infancy, childhood and adolescence ; and (3) the supply of the obstetri requirements of an adequate maternity service including antenatal supervision, skilful midwifery and postnatal care. The ultimate solution, the repor concludes, will come only through the gradual establishment of a higher standard of ordinary clinica midwifery practice, while the better physical conditio of the growing population should in time contribut materially to an improvement.

IRRIGATION AFTER PROSTATECTOMY

Sepsis after prostatectomy is nowadays receivin much attention, and urologists are making greate efforts to reduce this serious factor in mortality Dr. John Morton,[1] consulting surgeon to the Roya Prince Alfred Hospital, Sydney, points out tha catheter drainage of the prostatic cavity is unsatisfactory because of blockage of the catheter. T prevent it a large-sized catheter must be employed and this the urethra does not tolerate gladly. T overcome the difficulty, he recommends the use of a temporary drain through the perineum. A small midline incision is made in the perineum behind the bulb. Guided by two fingers of the left hand passed into the bladder from above, a closed clamp is pushed through the perineal incision into the prostatic pouch. The track is then dilated by opening the clamp, and a perforated drainage-tube is afterwards pulled through it and fixed so that one extremity lies in the prostatic cavity and the other outside the perineum. At the same time a fine irrigating tube is drawn up through the urethra and fixed to the bladder extremity of the perineal tube. By means of these tubes continuous irrigation can be carried out, the fluid entering through the urethral and leaving through the perineal tube. When the wash-outs are quite clear, both tubes are withdrawn.

---

[1] Med. Jour. of Australia, June 4th.

Mr. Andrew Fullerton, of Belfast, has already described a method of perineal drainage for septic cases, but Morton's has the advantage of providing for continuous irrigation.

BLOOD CHANGES AFTER IRRADIATION

THE inquiry instituted on behalf of the X Ray and Radium Protection Committee into the blood changes recorded in workers in radiological departments of various hospitals should provide useful data if the response to the questionnaire issued is satisfactory. The evidence will be collected this month and reviewed in October. Since the incidence of fatal cases of aplastic anæmia first drew attention to the development of blood changes elaborate screening precautions have been devised for the protection of workers, and stringent conditions for the storage and handling of radium have been laid down. It has moreover been the practice to insist on a holiday for those handling radium when the lymphocytes have fallen below normal limits, even though the health of the worker may be apparently unaffected. Lymphopenia is the accepted criterion of unequivocal damage, but it is possible that as a result of this inquiry a reliable danger signal will be found at a much earlier stage—for example, in the eosinophilia which accompanies the preliminary rise of the cellular content of the blood where blood counts have been charted for each affected individual over a prolonged period. It is more probable, however, that the inquiry will show that blood changes are so rarely encountered that the periodical blood counts previously recommended will be necessary only for those who come in close and frequent contact with radium or X rays. The answers to the questions should elicit from each hospital the proportion of those cases (if any) in which alterations of the blood have occurred to the total number of workers examined; records of typical blood counts in affected cases with details of the worker's occupation; and duration of service as well as notes on treatment. It is however through charts of consecutive blood counts on the same affected individual that most useful information on prophylaxis is likely to be obtained; in radium workers at least these may be found to follow if unchecked a typical curve, though the period during which the changes manifest themselves may vary greatly. In X ray workers Dr. Ch. Aubertin[1] described twenty years ago two types of count in radiologists and radiographers who had been at work from ten to fifteen years: in one type the leucopenia was chiefly of polymorphs and in the other there was a relative excess of polymorphs with eosinophilia. The treatment has hitherto been removal from contact with radium or X rays for a time. In the absence of any established form of specific therapy for aplastic anæmia it is difficult to suggest any other or to hazard an opinion how often the sequence of blood changes and holidays can safely be permitted. Fortunately, even in hospitals where nurses are constantly in attendance upon patients under treatment with radium, the proportion of those affected is believed to be very small, and in general hospitals where a change of personnel occurs every three months the chance of damage to the hæmopoietic system is probably negligible. But this circumstance should not produce a complacent attitude with regard to the questionnaire, for the need of further definite information is apparent. Sir Humphry Rolleston, reviewing blood counts in X ray workers in a critical review of the harmful effects of irradiation (X rays and radium) published last year,[2] pointed out that the blood picture seen after exposure to irradiation for long periods may differ from that obtained experimentally by one or a few X ray exposures, and that this might be considered to correspond with Warthin's observation that the bone-marrow becomes affected later than lymphoid tissues. He drew attention also to the conflicting observations on blood changes, which the information now sought may help to resolve.

THE ABORTIVE TREATMENT OF GONORRHŒA

PRINCIPLES to guide those prepared to attempt the abortive treatment of early gonorrhœa are laid down by Dr. Hansteen in the *Norsk Magasin for Laegevidenskaben* for August, 1932. The treatment should not be attempted if the infection has existed for more than six days, or in the presence of signs of severe irritation, with swelling and tenderness about the orifice of the urethra. The criterion by which he judged the results of his treatment was the disappearance or persistence of gonococci after the first examination. Among the patients with a first attack of gonorrhœa. dating only two to four days back, there were 12 successes and 12 failures. Among the patients whose infection dated five to six days back, there were 13 successes and 8 failures. A second group of patients included those who had previously had gonorrhœa once or twice. In this group among those whose infection dated only two to four days' back, there were 68 successes and 19 failures; among the patients in the second group whose infection dated five to six days back, there were 35 successes and 27 failures. Taking all cases together, 194 courses of abortive treatment yielded 128 successes and 66 failures. This by no means negligible measure of success was achieved by a comparatively simple ritual: thorough preliminary irrigation with 1 in 4000 permanganate of potash, followed by 2 per cent. protargol for five to six minutes, and finally treatment of the first 3 or 4 cm. of the urethra with pure protargol powder. The patient was instructed to give himself three injections of a 1 per cent. solution of protargol on the next day. The results were checked 10 to 12 days later. Though micturition provoked some burning on the first day, the patients willingly submitted to this treatment in order to achieve a rapid recovery, and in no case did a stricture or other serious trouble supervene. In this connexion it is of interest to recall that when some months ago the candidates for the vacant chair of skin and venereal diseases in Copenhagen had to deliver addresses on subjects chosen by themselves, one of the candidates, Dr. Svend Lomholt, chose as his subject the injection treatment of gonorrhœal urethritis in men, and he raised the question whether injections are useful in the treatment of uncomplicated gonorrhœa in men. Although his clinical experiences led him to answer this question in the affirmative, he held that convincing statistical evidence of the effectiveness of treatment by injections is lacking. In the absence of controls Dr. Hansteen's figures might not be acceptable to statisticians, but it seems unlikely that a consistently negative bacterial report would be obtained in so short a period after untreated attacks of proved gonorrhœa.

CHOLESTEROL METABOLISM IN EPILEPSY

CHOLESTEROL, as Mr. J. A. Gardner, F.I.C., reminded the B.M.A. Section of Pathology (see report on p. 577), is an integral constituent of all animal cells and body fluids. Its chemical relationships have been intensively studied, but hitherto its variations in health and disease have perplexed rather than enlightened the pathologist. A difficulty in investigating its metabolism lies in the fact that when released by the breaking down of the cells which contain it cholesterol is not excreted but is used in the formation of new cells. Our knowledge of its relation to arterio-sclerosis is now becoming more precise and, although no allusion to it was made at this discussion, the study of blood cholesterol in epileptic subjects is giving interesting results, impetus to the study having been given by the observation that a very high fat diet may control fits. Working at the State Hospital at Dixon, Illinois, Gray and McGee,[1] found the mean cholesterol content of the blood taken four hours after food in 29 observations on normal people to be 194 mg. per cent., in 312 observations on epileptics it was 163, and in 108 on feeble-minded it was 154. A total of 623 observations on epileptics, including blood taken at all periods after food, gave a mean result of 165. Their estimations were made, for the most part, on whole blood. A rise of cholesterol occurred frequently but not uniformly within the first hour or two after meals, and they conclude that a variation up to 30 or even 40 mg. per 100 c.cm. must be regarded as within the normal range for any individual. When however, averages of a large number of individuals are compared a difference of 10 mg. or even less may become of significance. With regard to fits, Gray and McGee find there is a definite low point (162 mg.) an hour after fits, the cholesterol gradually rising thereafter to a maximum of 172 when there has been freedom from fits for a month, though this figure, be it noted, is still considerably below that for the normal controls. All this tends to confirm the observations of Robinson, Brain, and Kay,[2] and of Gosden, Fox, and Brain,[3] and establishes the fact that blood cholesterol tends to be low in epilepsy, particularly just after seizures. No mention is made of the more vital and interesting problem of the pre-fit blood cholesterol. It might well be supposed that such a phenomenon as an epileptic fit would have complex metabolic results of an order that could be estimated. The important question is whether there are changes in the blood or cerebro-spinal fluid which precede the seizure and take a share in its determination. This point can only be cleared up by series of observations made at short intervals on the same patient for some hours before a fit occurs, or, not quite so satisfactorily, by a very large collection of observations made on a number of patients at varying intervals before fits have occurred. This principle applies to all metabolic investigations in connexion with epilepsy, but unfortunately as fits cannot be predicted with any certainty, serial pre-fit estimations can only be obtained occasionally after an immense amount of labour. Gray and McGee report some serial post-fit figures for cholesterol, which bear out the general results referred to above. A few serial pre-fit estimations were reported in the two papers published in our own columns, and these tended to show that the fit occurred near the bottom of a rather rapid fall in cholesterol content. The still lower level of blood cholesterol found in feeble-minded persons by Gray and McGee is striking. They make no comment upon it beyond suggesting that high fat diets might be desirable in institutions for these patients. The epileptic patients upon whom their observations were made were all hospital inmates. Their mental status is not specified, and the lowered cholesterol in their case possibly had relation with some condition other than the epilepsy. Further investigation might show a relationship between blood cholesterol and mental ratio.

DURABLE PEDIGREE SCHEDULES

FOR the study of morbid inheritance in man trustworthy records are essential. A schedule[1] already noticed in these columns has provided a uniform and adequate guide for this purpose. But it is not only morbid inheritance that needs to be recorded; normal and positive qualities, personality, attainments, intelligence, habits, and other such data are of relevance to the student of human genetics. In order that family pedigrees may be kept which will embody such information, the Eugenics Society has produced a larger schedule[2] which is designed to be filled in by intelligent persons desirous of transmitting to their descendants as full an account as possible of the members of the family in each generation. Such a record will be of the greatest value to any doctor called on in the future to give a genetic prognosis. The demand for a medical opinion on these points is steadily growing, but no system of recording pedigrees hitherto has provided the necessary data. The schedule is strongly made, with a buckram cover, and the paper is guaranteed to last for at least 100 years. All the parts are detachable, and specimen leaves and a reinforced vellum chart are provided, as well as full explanatory notes. Additional case-sheets, beyond the 30 included with the schedule, can be obtained as required. In making available so convenient and durable a pedigree schedule the Eugenics Society has rendered a service not only to genetics but also to preventive medicine.

STREPTOCOCCI

IT was in 1906 that Andrewes and Horder published their classical paper on the classification of the streptococci and gave a great impetus to the study of what have come to be the most important group of human pathogenic bacteria. Hygiene and serology have brought many microbes under at least partial control, but the streptococci have largely defeated the efforts of those who have sought to make out their modes of attack on the body or to treat established infections along specific bacteriological lines. Such studies must necessarily be based on the identification of the various kinds of streptococci which undoubtedly exist. Biochemical methods

ave proved inadequate, and various workers have ttempted to supplement them with serological tests with partial but quite unsatisfying success. It seems lear that the hæmolytic organism generally known s *Streptococcus pyogenes* and responsible for the bulk of serious human infections is a "good species" n the natural history sense. But it is equally plain hat the different strains of this species are no more dentical than the diseases which they produce, and t has been the concern of many bacteriologists to eparate and characterise them. It is on this quest hat the late Sir Frederick Andrewes spent the last even years of his working life, in coöperation with Miss Lettice Digby and with, later, Mrs. E. M. Christie; he died on Feb. 24th, 1932, leaving a characteristic account of his work almost complete, and this has now been finished by Mrs. Christie and his son, and published by the Medical Research Council.[1] It contains a wealth of technical detail about the methods and results of agglutination tests which will be of value to those working along similar lines. The main conclusions are, however, disappointing in that they lead to no clear-cut and definite criteria whereby the identity or diversity of different hæmolytic streptococci may be certified. Possibly agglutination is a method which is inapplicable in this particular group, and certainly both in their capacity to stimulate the production of agglutinating sera and in their reactions to the same the organisms seem to be perverse and froward to an inexplicable degree. It seems more likely, however, that the microbes are to an exceptional degree variable and adaptable, and that they are in a continual state of flux which may account for their varied capacities of invasion and pathogenic action. It may well be that as in some cœlenterates the different species and subspecies run into one another in a confusing way. Studied in the laboratory they certainly give this impression, and it is compatible with much of the epidemiological evidence, as Prof. C. C. Okell pointed out in his third Milroy lecture this year.[2] A solution will no doubt be reached some day, but for the present the relation of the gram-positive cocci to the body remains one of the most urgent and baffling problems of bacteriology.

CHOLECYSTOGRAPHY

ON another page the uses and limitations of cholecystography in the diagnosis of gall-bladder disease are clearly defined by Dr. James F. Brailsford. His article is founded on a large number of carefully studied cases, and his conclusions will be accepted by most workers in this field. His plea for careful attention to technique and detail should not be ignored, for many errors in interpretation creep in from a neglect of minutiæ. This is particularly true among ambulatory cases, for the patient is not under direct control for a varying period between the administration of the dye and the radiological examination; unauthorised food, to specify but one pitfall, may readily upset the result of the oral test. Dr. Brailsford's statement that the demonstration of a gall-stone in a radiogram does not of necessity mean the discovery of the cause of the pain, and that complete gall-bladder radiology gives the best indication of the condition of the gall-bladder requires a little amplification. Cholecystography must take its place with other methods of investigation; it has not rendered obsolete other aids to diagnosis. The clinical examination and, above all, the history extracted from the patient (the word "extracted" is used advisedly) must not be lightly disregarded in favour of a so-called positive radiological finding. It must be remembered that a normal gall-bladder may give no shadow and that one containing stones can fill and empty normally. A short course of rest combined with digitalis may make all the difference between the filling and not filling of a normal gall-bladder in a patient with a congested liver. The best method of administration is still in dispute. Intravenous injection of the contrast medium is, on theoretical grounds, the most reliable method of administration, since, by this route, the amount of dye which reaches the circulation is under complete control. Most observers therefore regard it as giving the most accurate results. In practice, however, more and more radiologists are adopting the oral route as the usual method of administration; it does not necessitate a night in hospital, there is less chance of severe reaction, and it is easier to carry out. Hitzrot and Pendergrass have shown recently[3] that in selected cases the intravenous route can be used safely in an out-patient department, the patient being sent home for the night. They add, however, that intravenous injection of the dye must not be used in a casual or haphazard manner, a conclusion we strongly endorse. Efforts are being made by variations in the technique of oral administration to obtain a greater concentration of dye in the circulation while maintaining the reduced liability to reaction. P. B. Davidson and his co-workers[4] give an intravenous dose of dye "sufficient to visualise the gall-bladder" but small enough to eliminate reactions, and follow this two hours later with a half dose by the mouth "for fortification of the shadow." They report good results from this method, and say that it can be used with safety in ambulatory cases. Sandström[5] aims at a cumulative effect by the oral route, for he gives the dye on two successive nights before making his radiological examination. Anderson and Marxer[6] have reported eleven cases investigated in this way, giving the full oral dose the first night and, if the shadow is absent or faint, a three-quarter dose the following night. Their series is too small to be conclusive, but it is interesting to note that of the eleven cases that gave no shadow after the first dose nine showed a normal gall-bladder after the second. If no shadow is obtained a repeated test is always a wise precaution, unless there is strong supporting evidence, for many observers have reported what may be called a temporary failure to get a shadow from a normal gall-bladder, whichever method of administration is used. In every cholecystography the rate and mode of emptying of the gall-bladder should be observed. Valuable information is often obtained this way, particularly in connexion with the influence of food. The value of cholecystography being now definitely established, a more settled terminology is overdue. The process is called variously cholecystography, the Graham test, the Graham-Cole test, the Cole-Graham test, and the dye test. Even the terms positive and negative are used in different senses by different radiologists; here a real danger lies, for "positive" may mean that the examination gave a pathological result or that a normal shadow was present. Similarly, "negative" is used to indicate either that nothing abnormal was noticed or, on the contrary, that no shadow was seen. "Filled and emptied normally" and "did not fill" are not much longer to write, and admit of no possibility of mistake.

BLOOD GROUPS: THE BURDEN OF PROOF

In the discussion on blood groups in our last issue (p. 528) it was pointed out that there is a difficulty in compelling a defendant to submit to the test. Evidence of blood groups would be chiefly valuable in bastardy proceedings which, though taking place before magistrates, are not of a criminal nature. Where actual crime is charged, the English law is remarkably tender towards the accused. There is an old maxim that no one is obliged *prodere se ipsum*, to give himself away. Thus any statement made by the accused before trial must be safeguarded by an elaborate caution so as to ensure that the statement is entirely voluntary. At the trial itself the accused can go into the witness-box, give evidence, and be cross-examined. If he does not do so, the judge may, but the prosecuting counsel may not, comment upon the omission. As regards evidence of what the accused has said before trial, the Court of Criminal Appeal has held that his silence is not to be relied upon as corroboration of an uncorroborated story. In another recent case that court gave an equally important ruling. The accused had received the formal statutory caution when before the examining magistrates. He had been told that he need not say anything if he did not desire to do so, but that whatever he did say would be taken down and might be given in evidence upon his trial. He then replied, "I don't want to say anything except that I am innocent of the charge." When his case came on for trial, the presiding judge's summing-up contained some adverse comments on this refusal to speak. An innocent man, he suggested, would have said frankly where he was and what he was doing when the offence was committed; if, he added, an accused man hangs back and postpones what he has to say till the eleventh hour, it is often because he wants to deny the police the chance of investigating his story and proving it false. The Court of Criminal Appeal said the summing-up was unsatisfactory; it was wrong to suggest that an accused person (who by a statutory formula is warned that he need say nothing) stands silent at his peril. The conviction and sentence of six months' imprisonment were quashed. So tender is the criminal law towards the accused. It follows that, if in a criminal case there were any question of an accused man's blood being tested, the law would be slow to exercise any compulsion. Nor would prosecuting counsel be encouraged—nor indeed would the judge himself probably see fit—to comment on the refusal to submit to a test.

ANÆMIA AND HOOKWORMS

At this year's annual meeting of the American Society for Clinical Investigation, C. P. Rhoads and W. B. Castle reported that a study of over 150 cases of hypochromic anæmia, associated with hookworm infection, in Porto Rico showed that intramuscular injection of red blood corpuscles caused increased blood formation, and concluded that it was logical to assume that the blood loss caused by the worms was significant as constituting a loss of potential hæmopoietic factors, and so producing defective blood formation. Neither elimination of the worms nor enrichment of the diet by meat and milk reduced the anæmia within the short examination period of two or three weeks, but the daily administration of 6 g. of citrate of iron and ammonia was nearly always followed by reticulocytosis, rapid increase in hæmoglobin and red corpuscles, and clinical improvement, and that despite the persistence of heavy hookworm infection and of a deficient diet. Liver was less effective than iron. Since in these cases of hookworm anæmia deficient diets were the rule and gastric anacidity frequent, it is suggested, in spite of failure of enriched diet to cause improvement, that dietary deficiency and gastro-intestinal changes are of major ætiological significance. It is of interest then to recall the massive clinical experiment made by Bailey K. Ashford and his colleagues in the same island, after the devastating hurricane of 1899 had left thousands homeless and starving. He reported[1] how, when he attempted to feed up on nutritious army rations those whom he thought to be suffering from the anæmia of malnutrition, they went down with diarrhœa; when fed plentifully on their own bulky diet their anæmia was unimproved; but when, after he had made his historic discovery that they harboured hookworms, he treated them with thymol, the result was very different. "As soon," he wrote of the campaign which followed, "as some notorious old anæmic, who had spent his last cent to buy iron pills, would return to his bario cured, the whole bario would swarm about our ears." Nothing could be more definite in this massive experiment than the failure of diet and iron and the success of disinfestation by thymol in curing the anæmia. A like experiment is taking place in Syria at the present time, for H. A. Yenikomshian and D. A. Berberian[2] have reported striking betterment after removal of hookworms when egg counts and worm recoveries had shown that few hookworms were present, in one case eight only. Here the species was identified as *Ancylostoma duodenale*. That the hæmopoietic structures can be stimulated to raise the quality of blood while the cause of its poverty remains is unquestionable; that it is in the interest of a patient to throw on these structures this extra strain instead of removing the cause itself, few medical men are likely to admit.

Mr. James Rögnvald Learmonth, surgeon to the Mayo Clinic, Rochester, Minnesota, associate professor of neurologic surgery in the University of Minnesota, has been appointed regius professor of surgery in the University of Aberdeen, in succession to Prof. Sir John Marnoch.

Central London Throat, Nose, and Ear Hospital.—The annual address will be given by Mr. Herbert Tilley on Friday, Oct. 7th, at 4 P.M., on the Nasal Accessory Sinuses. Lectures will be held at 4 P.M., on Fridays, every week during the winter session, beginning on Sept. 9th, when Mr. M. Asherson will lecture on indications for operations on the mastoid. Subsequent lectures will be noted in our Medical Diary.

British Hospitals Contributory Schemes Association.—The annual conference will be held at Torquay from Sept. 22nd to 25th. It will be attended by Dr. René Sand, of Paris, president of the International Hospitals Association, who will discuss the methods by which hospitals are maintained in various parts of the world. Delegates will attend to represent contributory schemes from all parts of the country.

SPECIAL ARTICLES

THE PATHOGENESIS OF MENTAL DEFICIENCY

By A. G. Morison, M.D., D.P.H.
DEPUTY MEDICAL OFFICER OF HEALTH, BRISTOL

The following observations are made after a study of 84 consecutive and personally investigated cases of mentally defective children. In every case inquiry was made in regard to insanity, attendance at special schools, nervous disorders, epilepsy, illegitimacy, and alcoholism in the families of both parents, and in the brothers and sisters of the children. The health of the mothers during the pregnancies and any accidents or upsets to their peace of mind were considered, as well as the full life-histories of the children themselves.

ENVIRONMENT AND HEREDITY

The children came from homes which were classified thus: (1) easy and comfortable, with good intelligence of the parents, in which the children had been well cared for since birth; (2) casual, the parents being of poorer intelligence, but not neglectful of the children; (3) more casual and thriftless homes, with parents of poor intelligence and evidently neglectful of their children.

TABLE I.—*Environment and Defect*

Group.	Comfortable.	Casual.	Neglectful.
Idiots	2	—	—
Imbeciles ..	19	2	—
Feeble-minded ..	23	31	7

Table I. shows that the lowest grades of all had had better surroundings from birth than the others. In 62 per cent. of the feeble-minded, the home surroundings were casual or neglectful, the corresponding figure for the imbeciles and idiots being only 8·7 per cent.

In the lower-grade group (notifiable to the local mental deficiency authority) the family histories were completely healthy in exactly 50 per cent. of the cases. Mental defectiveness appeared in nine cases, in five cases one of the parents being feeble-minded. In the 34 families of this group there were 113 living children, 37 (that is 32·7 per cent.) of whom were defective, and in 3 cases only did the children have a defective brother or sister.

In the higher-grade group (not so notifiable) the family histories were healthy in only 36 per cent. of the cases. Feeble-mindedness itself was present in 25 of the family histories, for both parents were feeble-minded in 2 cases and one parent in 13 cases, and mental defect was otherwise present in the family histories of 10 other children. These 50 children belonged to 49 mothers who had in all 188 living children, 63 (that is 33·5 per cent.) of whom were defective, and in 14 cases the children had defective brothers or sisters.

Regarding a family history of mental defectiveness, then, these points emerge: (*a*) in the lower grade 26 per cent., and in the higher grade 50 per cent., had such a heredity; (*b*) there were 8·9 per cent. siblings in the lower grade, but 28·6 per cent. in the higher grade.

FORM OF BIRTH

In the case of 75 children the birth was natural, instrumental aid being applied in 9 cases. Six low-grade children call for further comment. For, in every one the family history was untainted, the mother was of high intelligence, the pregnancy throughout was uneventful, but in 4 cases severe fits commenced within a few hours of birth, in the fifth case the head of the child "was out of shape for three weeks," and the sixth case was one of placenta prævia, terminated by instruments without anæsthetic because of the mother's excessive hæmorrhage. All the children were males; one was a cerebral diplegic, one a spastic paraplegic, one had a monoplegia (left arm), and four of these six children continued to have fits.

POSTNATAL ILLNESS

Of the lower-grade children three had had encephalitis, two suffered from fits (both commencing at about eight months of age), one had had cœliac disease, and one had had whooping-cough when three months old. (One night he coughed until blood ran from his ears, nose, and mouth.) He was a deaf mute. Five higher-grade children seemed to have had their development arrested in the following ways, three by fits (one so afflicted at six weeks, one till two years old, and one between two and three years), one was a case of dyspituitarism, and perhaps a fall out of his perambulator at the age of seven months had seriously affected another.

SOME OBSERVATIONS ON THE CHILDREN

The male sex predominated, more especially in the higher-grade cases (Table II.).

TABLE II.—*Sex-incidence*

Sex.	Lower-grade cases.	Higher-grade cases.	Total.
Male ..	20 (58·8 %)	32 (64 %)	52 (61·9 %)
Female	14 (41·2 %)	18 (36 %)	32 (38·1 %)

The children commenced to walk at times shown in Table III. As well as never reaching to normality, the defective seems generally to develop more slowly than the normal, such retardation being still more marked and of a greater significance, however, in the development of speech.[1]

TABLE III.—*Time of First Walking*

—	Under 18 months.	18 mths.–2 yrs.	2–3	3–4	4–5	Over 5	Still cannot walk.*	Age unascertainable.
Lower grade	12, or 35 %		3	10	2	3	4	—
Higher grade	21	10	12	1	—	—	—	6
	31, or 62 %							

*All aged over 7.

CRANIAL CIRCUMFERENCE

Tredgold[2] gives a table of the normal cranial circumference for age and sex. 79·4 per cent. of the low-grade cases had a cranial circumference appreciably less than this normal, and in 20·6 per cent. this normal was exceeded; 64 per cent. of the higher-grade children failed to reach the average measurement, 22 per cent. were normal, and 14 per cent. exceeded normality.

---

[1] Morison, A. G.: The Lancet, 1932, i., 931.

[2] Tredgold, A. F.: Mental Deficiency, London, 1929.

These findings are in agreement with the general observation that in physique also the mentally defective is subnormal. He often looks, as he is indeed, younger than his years.

ORGANIC NERVOUS SYSTEM

The organic nervous system was normal in 56 per cent. of the lower-grade and in 88 per cent. of the higher-grade children. In the first group, three suffered from cerebral diplegia (one with athetosis), three others from spastic paraplegia, two from hemiplegia, one from monoplegia (left arm), and there were two in whom the only abnormality elicited was a unilateral extensor plantar reflex. One case showed a mid-brain lesion, and another had ataxia of one arm. One girl showed a general amyotonia which was evidently improving (she was then aged 7 years, it may have been amyotonia congenita), and in another child there was only a poor balance generally. In the second group, one child showed ataxia of the right arm, one had not then (aged 5 years) gained full coördination of the muscles of the pharynx. In another, there was general muscular atonia, and in three others a poor balance.

Sixteen, or 47 per cent., of the first group showed strabismus; 11, or 22 per cent., of the second group were similarly affected. Amongst 7222 children examined in the ordinary schools, 1·39 per cent. showed strabismus.

OCCURRENCE OF FITS

Amongst the low-grade children, 19, or 55·9 per cent., had never had a fit, 12 remained subject to fits, the 3 others each having had one isolated fit. Amongst the higher-grade children, 84 per cent. of the group had never had a fit, and only one of the group remained subject to fits. Amongst 7222 children attending ordinary elementary schools, a history of fits was elicited in 0·16 per cent.

CONCLUSIONS

There are appreciable differences in the ætiology of mental deficiency in its lower and higher grades. For, in this review, prenatal causes (including heredity) accounted for 47 per cent. of the lower grade, but for 72 per cent. of the higher grade. Circumstances of delivery were connected with the defectiveness of 17 per cent. of the lower grade, while such circumstances could not be connected with the defectiveness of any of the higher grade. To postnatal illnesses were attributed 21 per cent. of the lower grade, but only 10 per cent. of the higher grade.

Sterilisation has but a very limited application in the prevention of mental deficiency in its lower grades. For the lower-grade children appear often where least to be expected, and their presence in a family is no proof of an inability of the parents to beget normal children. Amongst the higher grade, sterilisation would certainly prevent the births of a number of feeble-minded children. But it is to be noted that all defective children do not have a defective parent, and it is no more true that these parents have only mentally defective children.

The majority of the mentally defective are of the male sex.

As a class mentally defective children are also physically subnormal; and they are stigmatised, maimed, and scarred, the more so as is their defectiveness more pronounced. But there is no pathognomonic physical sign of mental deficiency.

MEDICINE AND THE LAW

The Lübeck Trial: Judge's Suicide

QUESTIONS of the mental fitness of a judge do not often occur. The judicial handling of a trial may be reviewed on the grounds of mistake as to the law, misunderstanding of the facts, wrong admission or exclusion of evidence, and even partiality or bias; but it is rare to find a result challenged on the ground that the judge was not in full possession of his senses. This seems to have happened in the Lübeck proceedings, where two doctors were sentenced to imprisonment in February last on charges of negligence, involving the death of some 70 infants who had been subjected to the Calmette vaccine process for tuberculosis immunisation. Dr. Wibel, the presiding judge, suffered a nervous breakdown after a long and complicated trial. He is now reported to have committed suicide; it is suggested that he had become aware of the fact that defending counsel had put forward as one of the grounds of appeal the allegation that he was not in a fit mental state at the trial.

If a similar situation arose in criminal proceedings in England, there would be no need to raise the question of the judge's mental capacity. The Court of Criminal Appeal would be in possession of a verbatim report of the judge's summing-up and of the evidence. These would furnish sufficient material for deciding the appeal without recourse to medical evidence of the judge's state of mind. If defending counsel thought that a defendant's chance of a fair trial had been prejudiced by judicial incapacity after this fashion, it would be their duty to say so fearlessly. An English court does not lightly tolerate any reflection upon the capacity of an English judge; "scandalising a judge" is a form of contempt of court; but what counsel say in court is privileged as regards actions of defamation. If a judge were known to be losing his grip of judicial work, the fact would hardly escape the knowledge of appellate tribunals, which would doubtless examine his decisions the more carefully. But there have been judges who, while apparently disposed to slumber on the bench, have usually known how to be wakeful at the right moment. In the last resort an incapable judge can be removed in England by a resolution of Parliament. This weapon is rarely needed.

PARIS

(FROM OUR OWN CORRESPONDENT)

VERDUNISATION OF THE WATER-SUPPLY

Mr. Justin Godart, Minister of Public Health, has recently inaugurated at the communal station of Ivry the new special installations for providing Paris with potable water. Parisians have for over six months been enjoying the benefits of their new water-supply, the purity of which they owe to Philippe Bunau-Varilla. He has played a remarkable part in the public health administration of his country. Attached to the army of Verdun, he devised the chlorine process of water sterilisation to which he has given the term "verdunisation," and has refused to take out any patent in connexion with the process. Bunau-Varilla has for many years been the fervent apostle of drinking water reform throughout France. In July, 1929, he presented a report[1] to the authorities concerned with the water-supply of Paris, challenging the dictum that Paris was already supplied with pure water which had no bad taste and brought no danger of enteric fever. His reply was a flat denial that Paris was protected against an epidemic of enteric fever. He pointed out that Paris had two water-supplies, one of which was non-potable and was intended only for industrial purposes. This water, the consumption of which was admittedly dangerous, was actually contaminating the drinking water-supply. In spite of the efforts of the municipal services, more than one source of contamination was discovered almost every month. Bunau-Varilla was therefore moved to press for the verdunisation of contaminated river water; and it is thanks in large measure to his consistent advocacy of this reform that Paris in 1932 has at last achieved a reasonably safe supply of drinking water. The history of the purification of the water-supply of other towns in France has recently been told in the *Siècle Médical*. Rheims, for example, had, before the war, an average enteric mortality of 12·4 per 100,000 inhabitants. By 1930 its enteric mortality had been reduced to zero, where it has remained ever since. Another town to anticipate Paris in the verdunisation of its water-supply is Lyon which, in 1926 and 1927, had an enteric mortality of 3·16 per 100,000. In 1928 the great epidemic raised this mortality to 9·3, and it was still as high as 8·43 in 1929—the year when verdunisation was introduced. By 1931 the enteric mortality of Lyon had been reduced to 0·88 per 100,000. The extraordinary difference between the enteric fever mortalities per 100,000 of Paris on the one hand and London and Berlin on the other are to be seen in the following table:—

THE PERMANENT WAVE INDICTED

In a recent communication to the Academy of Medicine, Dr. André Feil, of the Institute of Industrial Hygiene, criticised the processes by which straight hair acquires a permanent wave. This criticism is, by the way, not new; as early as 1930 the same subject was discussed at a meeting of the Spanish Health Society. Dr. Feil's account of the dangers run by the aspirants to wavy hair need hardly make it stand on end, for his indictment is limited. It is true that during one stage of the complicated process the client experiences a sensation of local heat which may be extremely disagreeable, particularly in hot weather. This sensation may, it is said, be followed by one of fatigue and heaviness of the head. In most cases these local and general symptoms last only a day or two; and if the matter ended there, the hairdresser's clients would assuredly consider their sufferings negligible. But Dr. Feil pushed his attack on the permanent wave home with the record of a case, the fatal issue of which he was inclined to trace to the waving operation. The patient was a girl of 13, apprenticed to a hairdresser who, having just bought a new apparatus, tested it on his apprentice. She had previously shown no premonitory signs of meningitis. It was a hot summer's day, and the electric current failed during the application, which was continued beyond the time limit indicated by the instructions. During the operation the girl sweated freely, complained of the heat and of headache, and begged to be set free from the apparatus. During the following days she suffered from attacks of giddiness and headache which were followed by vomiting. She remained at work for some days; then, obvious signs of meningitis supervening, she was admitted to hospital. Death occurred a month from the date of the permanent waving, after a period of delirium and coma. Dr. Feil suggests that death was due to tuberculous meningitis precipitated by the permanent waving, though no tubercle bacilli had been found in the cerebro-spinal fluid. Though he considers the operation of permanent waving safe enough when carried out under proper conditions on a healthy person by a skilled hairdresser, he deprecates the application of this process to subjects of pulmonary tuberculosis, on the grounds that tubercle bacilli might become localised in the meninges. His list of contra-indications includes epilepsy, advanced age, arterio-sclerosis, and high blood pressure, lest the high temperature should favour a cerebral hæmorrhage.

HOT-BOTTLE BURNS DURING GENERAL ANÆSTHESIA

A recent decision in the law courts concerns a patient who, having been operated on for appendicitis, was taken back to her room, where she was left in the care of a nurse. Obeying instructions, the nurse put a hot-water bottle so close to the legs of the still unconscious patient that severe burns ensued. An action having been brought against the surgeon and physician in charge, the court ordered two experts to present a report on the case. They put the blame on the nurse, holding the doctors in charge not responsible. The court having given judgment in accordance with this report, the patient appealed against its decision with the ultimate result that the doctors were held responsible, damages of 6000 francs being awarded against them.

(FROM OUR OWN CORRESPONDENT)

DISTRIBUTION OF SWEEPSTAKE FUNDS

SOME weeks ago the Minister for Justice of the Irish Free State gave instructions for the disbursement to the participating hospitals of one-third of the amount available from the Manchester November Handicap Sweepstake. He has now given instructions for the disbursement of 95 per cent. of the remaining two-thirds, the small balance outstanding to be retained by the trustees for the present. It is understood that the 5 per cent. is retained pending the settlement of an objection raised by one of the hospitals. The amount available for the voluntary hospitals from the sweepstake was about £493,000, but for the purposes of their calculations the committee worked on a basis of the round sum of £500,000, the proportions of which allotted to some of the principal hospitals are as follows:—

	£
Children's Hospital, Temple-street, Dublin ..	22,770
Coombe Lying-in Hospital, Dublin	17,820
Mater Misericordia Hospital, Dublin	29,155
Meath Hospital, Dublin	18,860

WHOLE-TIME MEDICAL OFFICERS

Dr. Thomas F. O'Higgins, the county medical officer of health for Meath, is also a member of the

Dáil. At a recent meeting of the County Meath Board of Health, the propriety of Dr. O'Higgins's political activities was questioned by the chairman of the Board and by some of the members. Dr. O'Higgins said that he was conscious of his responsibilities as a public officer, and that he fulfilled his duties as such. If it were proved that he were not carrying out his duties satisfactorily he would resign, but as long as he was carrying out his duties he would spend his spare time as he chose. In a letter to the press on the meaning of the term "whole-time medical officer," Dr. T. Hennessy, medical secretary of the Irish Medical Committee, states that "whole-time" meant simply that a county medical officer of health shall devote his professional services entirely to public health work, and not engage in private practice. Such a provision is intended to ensure the independence of the medical officer of health. "Before and after the working hours necessary to discharge their duties," Dr. Hennessy concludes, "county medical officers of health are free to take part in politics, farming, or even dog-racing if inclined that way."

IRISH MEDICAL MEN ON OLYMPIC COUNCIL

Among the members of the Irish Olympic team returning from the Olympic Games at Los Angeles, Dr. Patrick O'Callaghan, assistant medical officer at the Clonmel Mental Hospital, was welcomed at a public reception and dinner in Dublin on August 27th. He won the hammer event at the games, and was the only winner at Los Angeles who retained the championship won at the previous games at Amsterdam. His performance was some eight feet better than at Amsterdam.

Sir William Wheeler, who has been surgeon to Mercer's Hospital for 28 years, has left Dublin, and intends to practise in future in London. He has accepted appointment as one of the surgeons to the new Southend Hospital.

UNITED STATES OF AMERICA

(FROM AN OCCASIONAL CORRESPONDENT)

CONTROL OF PELLAGRA

MANY in this country are still unwilling to regard pellagra simply as a deficiency disease, partly perhaps because the brilliant experimental work of Goldberger and his associates is so slow in bringing practical results. At a recent meeting of the American Medical Association in New Orleans, two surgeons of the U.S. Public Health Service pointed out[1] that of the 7146 deaths due to pellagra in 1930, 7000, or 97·9 per cent., occurred in those States which lie wholly or partially within the cotton belt, and most of the cases were found in that portion of the cotton belt actually engaged in the production of cotton. Whilst this very high mortality persists, and the morbidity is said to be actually increasing, the disease has already come under control in institutional life. The largest insane asylum in the south has reduced its pellagra mortality from 6·2 per cent. of all inmates to less than 0·1 per cent. Up to the present 35 foodstuffs have been tested by the public health service to determine their value as preventives of pellagra. Of these, milk, fresh beef, canned corned beef, liver, canned salmon, canned haddock, tomatoes, turnip greens, and canned English peas have each been found to prevent pellagra when added in sufficient quantity to an otherwise pellagra-producing diet. Dried yeast and commerical wheat germ are good sources of the P.-P. vitamin and are recommended for use in emergency. It is in late winter and early spring that the people in the cotton belt need supplementary foods. The Department of Agriculture backed by the agricultural colleges with their extension services, and generously aided by the newspapers, has long supported a programme of diversified farming. Progress has been very slow, and many believe the only hope of controlling this preventable disease to be in controlling the price of cotton.

CONSUMPTION CURE FOUND FRAUDULENT

When the United States supreme court decided some years ago, in a divided opinion, that the words "false or misleading in any particular" in the Food and Drug Act referred only to the composition of the drug and not to therapeutic claims made therefor, a serious blow was struck at the efficacy of the Act in controlling the sale of secret remedies. To repair the damage wrought by this decision, Congress passed the Sherley amendment in its original form; this amendment declared a medicine misbranded when "false or misleading" claims were made. But the enemies of public safety were successful in getting this phrase changed to "false and fraudulent." It is now necessary, therefore, to prove to the jury not only that the claims made by the manufacturer are misleading to the public but that they were intended by him to mislead the public.

A remedy for consumption, rheumatism, lumbago, croup, and other diseases was originated by one W. P. McClellan, who owned a livery stable and used the remedy on his horses. This remedy, known as B. and M., is a simple liniment of, essentially, turpentine, ammonia, and egg. The federal government brought a case against B. and M. in 1922 and lost it. After 10 years, on July 19th, 1932, again at the instance of the federal government, this nostrum has been declared misbranded in the federal district court at Baltimore. During the trial the B. and M. concern called a number of witnesses who alleged that they had been benefited or cured by the use of the liniment. The government was able to prove, however, that those who had had active tuberculosis still had active tuberculosis. A testimonial widely used by the B. and M. concern had been written by a consumptive who at definite intervals received cheques from the concern, and who eventually had died of his disease.

The judge in his instructions to the jury expressed two opinions of considerable importance. The first, supported by a quotation from a supreme court pronouncement, is that persons who make or deal in products alleged to have curative powers are in a position to have, and are expected to have, superior knowledge of the preparation and marketing of such articles. The second is that the simple assertion by a manufacturer of his faith in the virtues of his product is not to be construed as proof of good faith when the manufacturer's opinion is contrary to an overwhelming mass of expert testimony.

POST-VACCINAL ENCEPHALITIS

Of the 700 cases of this disease on record, 71 have been recorded in the United States during the last years. It has not been found possible to incrim- ate any particular method of vaccination or any rticular batch or strain of vaccine virus ; cases have llowed the employment of calf virus from 10 out of total of 18 vaccine establishments. Two out of e 71 cases are reported to have followed a second accination. All cases, except one, followed single sertion vaccinations, this being the technique mmonly employed in this country. Dr. Charles rmstrong, of the U.S. Public Health Service, has rought forward a theory, based partly on previous oservations and partly on his own experimental ork, that a previous "non-specific" stimulation of the body's defence mechanism may tend to prevent post-vaccinal nervous complications. He has shown that if a preliminary injection of toxoid is given to white mice, who are subsequently given an intracerebral injection of vaccine virus, there are more survivals in the toxoid immunised groups, and also the toxoid treated mice tend to die later than the controls. It is suggested that a similar protection may be conferred in man by the following technique : the first dose of toxoid is given at six months of age and the second dose one month later. Vaccination against small-pox is given three to four weeks after the second inoculation with toxoid.

PANEL AND CONTRACT PRACTICE

Usual Occupation

"A man must be capable of doing his own work or lse he was not capable of work." This statement, ttributed by the *National Assurance Gazette* to)r. H. G. Dain, chairman of the Insurance Acts Committee, is of course perfectly correct in assessing *n the first instance* any insured person's capacity or ncapacity for work. This principle was recognised n Memo. 307/IC issued by the Ministry of Health, where it is stated that an insured person might be egarded as incapable of work by reason of specific lisease or bodily or mental disablement when he is in uch a condition that an attempt to work would be eriously prejudicial to his health; and *secondly*, hat he should be regarded as totally unfit if, as will ordinarily be the case, it appears probable that he will soon be able to resume his former work, and that t would therefore be unreasonable to expect him to take any other form of work in the meantime. The last part of this clause, however, indicates that Dr. Dain's words were not intended to be a complete statement of the position. It has never been contended that because (say) a 'bus-driver loses a limb as a result of accident, and thereby becomes for ever incapable of driving a motor-bus, he should be written off as permanently incapable of work, and approved societies are frequently referring cases to regional medical officers for an opinion whether the insured person could not now be considered fit for some other gainful occupation. This opinion may be easy to give or it may be beset with difficulties. For instance, a farm labourer living in a small village contracts Bright's disease with some secondary bronchitis. The examining officer might easily come to the opinion that he was capable of doing something, such as clerical work, not involving exposure to cold or damp ; but what chance would there be of this man being able to find this work in a small village, or that he would be mentally able to do it. Other cases which are always giving trouble about incapacity are epileptics and asthmatics ; both are quite incapable of work during periods of attack, and in the great majority of cases both are fit to work within a relatively short time after the attack is over. Epileptics are only capable of work "not involving danger to themselves or others," and in both types the frequency of attacks is the crucial factor in deciding whether they are fit to work at all. In such cases it becomes simply a matter of who is to pay for their maintenance. If, as the *Gazette* says, the doctor certifies them incapable then the N.H.I. funds pay; if they are marked not incapable, being fit for something which has a restricting clause added "not involving so and so," they become chargeable to unemployment funds, if they are in an insurable occupation ; and if not, being unable to obtain work, they eventually come under the care of the public assistance committee.

NOT UNFIT FOR HOME WORK

The difficulty of married women's incapacity, which was so prominently brought to the notice of the profession recently, has resulted in a departure from the usual form of certificate issued by the regional medical staff to doctors and to societies. It will be remembered that the claims of married women for sickness benefit had more than doubled, and societies were put to it to do something to cut down these excessive claims. Many married women were coming under the Act as a result of one or two days' occupation per week, only to be certified as incapable of charing, or some quasi part-time post, owing to some incapacity, either temporary like pregnancy, or possibly permanent like rheumatoid arthritis ; frequently these people were thought by sick visitors to be quite capable of doing unaided the ordinary household work at home. Societies have now come to an understanding with the Ministry, under which they can obtain the opinion of its regional medical staff as to whether an insured person is capable of doing unaided her ordinary household duties. The form of words used in the reports, both to societies and doctors runs : ". . . is unfit at present to resume her former occupation but is not unfit for the ordinary daily work of her home," the words "incapable of work" on the usual form of report being erased. There has been no communication from the Ministry of Health to the profession generally, nor to panel committees, authorising insurance practitioners to alter Form Med. 40 (the ordinary certification form) in any way. On that form the doctor has to certify either incapacity or fitness to resume, and it is held to be a breach of the terms of service to alter it. The position appears to be that the regional medical staff may give opinions to approved societies on these cases whilst the practitioner in attendance is not permitted by law to do so.

A CITY DISPENSARY.—Under a scheme which has been sanctioned by the Charity Commissioners the Royal General Dispensary in Bartholomew-close, London, founded in 1770 by John Lettsom, is to be merged into St. Bartholomew's Hospital. The transferred property consists of the freeholds of 24, 25, and 26, Bartholomew-close, which is occupied partly by the charity and partly by a tenant who pays a rent of £450. The dispensary is to occupy part of the hospital building at a rent fixed by a valuer, and the medical and secretarial work will be done by the hospital in return for an annual payment. Should it no longer be possible usefully to carry on the dispensary section of the charity, its clear yearly income will be transferred to the hospital so long as the work of visiting out-patients at their homes is continued within the dispensary's area.

CORRESPONDENCE

CARBOHYDRATE CONTENT OF FOODS

To the Editor of THE LANCET

SIR,—Since our return from holiday we have been interested to notice the correspondence in your columns (pp. 372 and 420) about the carbohydrate food values published by us in 1929. We are glad to see that the analytical accuracy has not been challenged. We admitted frankly at the time of publication that our figures were far from perfect, but that we believed they represented the best approximations to the truth so far obtained, and this statement has remained uncontradicted for three or more years. Previous food tables were very largely based on the American analyses of 1899 in which the carbohydrate was determined "by difference." Our figures which tried to differentiate available from unavailable carbohydrate differed enough from the older ones to affect diabetic therapy, since the older figures for carbohydrate included in many instances large amounts of carbohydrate material which was not absorbed and metabolised as carbohydrate. Most American authors have completely ignored the newer figures and have continued to use the older ones, whereas the German, Scandanavian, and some British authors have advanced to the 1929 tables as indeed, we believe, ought generally to be done until we, in our turn, are shown to be wrong and our work out-worn.

We are, Sir, yours faithfully,

R. D. LAWRENCE,
R. A. MCCANCE.

SPLENECTOMY FOR SPLENO-MEDULLARY LEUKÆMIA

To the Editor of THE LANCET

SIR,—In your issue of Sept. 3rd (p. 516) you report that Lord Dawson stated, at a recent discussion on the indications for removal of the spleen, that apart from trauma and rare tumours there are three diseases only in which splenectomy is justified—acholuric jaundice, purpura hæmorrhagica, and splenic anæmia. With the exception of McNee's statement, later in the discussion, that he includes the majority of leukæmias in his list of conditions in which splenectomy is contra-indicated, I find no reference to leukæmia. Lord Dawson's statement prompts me to send you a preliminary note of a married woman, aged 36, in whom splenectomy was this year deliberately performed for the relief of myeloid leukæmia. I understand that it is the first case of the kind in Westminster Hospital. The immediate result has been dramatically successful, but I propose to wait for a year before submitting a full account for publication.

The patient, who had been ill for a year, was admitted on May 10th. The spleen was enormous, the liver a little enlarged; but apart from the state of the blood she showed no evidence of disease. She was weak and breathless, due as much to the splenic bulk as to a moderate anæmia. The myelocytes were 76 per cent. of 150,000 white cells per c.mm. Between May 10th and 23rd, during which period she was confined to bed and given iron and arsenic by mouth, the white cells increased to 195,000; the myelocytes decreased however to 27 per cent. The spleen was then treated with radium, and liveroid was substituted for the iron and arsenic. On May 30th, after four applications of radium, the curve of the leucocyte count had fallen sharply. She had 46 per cent. myelocytes of 54,000 white cells. On June 18th, after a total of 11 applications of radium, and liveroid, the myelocytes were 16 per cent. of 60,000 white cells. This count was made immediately before operation. She felt neither better nor worse, and the spleen, although considerably reduced in size, was very large. Although the number of myelocytes had steadily decreased, the total number of leucocytes which had fallen so dramatically in conjunction with the first few applications of radium showed no further tendency to fall and remained about 60,000. It seemed that radium had done all it could for the time being. As I was unable to convince myself that splenectomy, certainly at this stage, had any claim to be harmful I accepted the alternative—namely, that it should be beneficial, although this view seemed opposed to general teaching. Accordingly, I asked Mr. Rock Carling to operate, and he did so on June 18th. Hæmorrhage was trivial and adhesions few. The spleen weighed 3½ lb. and showed a single yellow infarct, but not at the site of the adhesions. There was a sharp post-operative rise in the leucocyte curve to 75,000 (myelocytes 21 per cent.) within two minutes of ligaturing the pedicle and removing the spleen. After this rise the curve fell equally sharply, and on July 1st, two weeks later, the myelocytes were 8 per cent. of merely 8500 white cells. Further treatment specific to the disease is contemplated, but none of any kind has been given since the operation. On July 20th, the day of her discharge, the myelocytes were 4 per cent. of 8100 white cells, and on August 9th, on her return from convalescence, they were 2 per cent. of 7500 white cells. She said that she felt very well.

Osler (1910) wrote that splenectomy of the leukæmic spleen had been performed 43 times with 5 recoveries, but he did not state the type of leukæmia. In spite of this I have been brought up to accept the teaching that splenectomy in myeloid leukæmia is uniformly fatal from collapse or hæmorrhage. I quote this statement from Taylor's "Practice of Medicine" (1925). Surgery seems to be contra-indicated, not because of its failure to prevent relapse and ultimate death, and not because of the futility of treating a part only of the tissue which is diseased, but because operation is directly fatal. But from my experience of splenectomy in other conditions in which the spleen is diseased and enlarged, I have not understood the reason for supposing that collapse or hæmorrhage will occur specially in the surgery of myeloid leukæmia, and with such particular fatality. The cause of collapse, apart from the duration of the operation in a sick patient, may be supposed to depend in part on the too rapid expansion of compressed abdominal vessels. Hæmorrhage, severe enough to kill, may by inference be anticipated chiefly from vessels within adhesions. But surgeons deal with these matters successfully when they remove other abdominal masses.

I am, Sir, yours faithfully,

HILDRED CARLILL, M.D. Camb.,
Physician to Westminster Hospital.

Harley-street, W., Sept. 3rd, 1932.

THE INCREASE IN ARSENIC-RESISTANT SYPHILIS

To the Editor of THE LANCET

SIR,—While agreeing with Dr. Burke's main contentions I must demur from attempts to find a formula, with mathematical exactitude, as to the quantity of treatment required to cure syphilis. I am certain Dr. Burke will agree with me that it is not syphilis but syphilitics we are to treat, and that no two cases are similar. Bearing this in mind I would ask Dr. Sequeira what "authority" would have the courage to state with exactitude what constitutes adequate treatment. I know of no disease where a therapeutist would state with accuracy the quantity of drug required to cure that disease, yet one attempts to do so in syphilis where the ravages are so protean. Can Dr. Burke tell your readers with certainty the life-history of the spirochæte; can he even tell at what stage of this life-cycle (if there is one) the primary sore develops; can he tell us whether all are infected with a similar strain or even how long the disease remains focal? This being so, is it not preferable to have a working basis of treatment, and to treat individuals as necessity demands?

I am, Sir, yours faithfully,

London, W., Sept. 5th, 1932. M. W. BROWDY.

"QUINSY-VOICE WITHOUT QUINSY"

To the Editor of THE LANCET

SIR,—In a letter published in THE LANCET July 16th (p. 158) Sir James Dundas-Grant asks if others have noticed the "quinsy-voice" in cases of œdema of the pharynx or larynx without quinsy. On two occasions recently I have examined patients with this symptom. Each time before inspecting the mouth I had remarked to my clerk that here is a case of quinsy and I was astonished to discover that in each case the view from the mouth was normal. On laryngoscopy, the first case showed œdema of the epiglottis, the second case swelling of the back of the tongue. Both recovered in a few days with inhalations, adrenaline injections, salicylates, and fomentations to the neck. I have never met the symptom before.

I am, Sir, yours faithfully,

A. BRAMWELL COOK, F.R.C.S. Edin., M.R.C.P. Lond.,

Medical Officer in Charge, Emery Hospital,
August 17th, 1932. Anand, India.

INTERMITTENT HEADACHE IN WOMEN

To the Editor of THE LANCET

SIR,—After reading Dr. A. P. Thomson's paper in your issue of July 30th I came to the conclusion that I had been entertaining angels unawares, in that a case in my care showed the syndrome described by Dr. Thomson.

The patient, an intellectual and critical woman of 33, first described her symptoms to me in June of this year, when I happened to see her during an attack. The headaches develop regularly on the day before her period, the periods being scanty but regular, with a 28-day cycle. On the day before the menstrual flow begins she wakes with the impression that her sight is obfuscated, and that acuteness of vision is reduced by about half; there are no fortification images. She creeps about until midday, by which time the headache is in full swing and she is obliged to retire to bed. Light becomes unbearable to her, and the pain is intense; at first diffuse, it later settles down in the region of the left temple, just above the zygoma. Nausea often accompanies the pain, but she never vomits during the attacks now, though previously she did so. She lies, she says, "dead still, waiting for the evening," her experience being that the pain goes with the daylight.

There is a perfectly definite moment at which the pain begins to abate, associated with what she describes as "a small physical movement inside the head." She tried to illustrate this sensation to me by holding two matchsticks vertically between finger and thumb, and clicking one past the other. From the instant at which she experiences this movement the pain begins to ebb, and by the end of two hours it has disappeared entirely. By this time it is usually 10 or 11 o'clock at night; she feels at once relieved, exhausted, and very hungry. During the attack she passes frequent formed motions and large quantities of pale urine.

She cannot recall having these headaches before the age of 18, though she remembers several outstanding attacks of the kind at or about that age. Since her marriage at the age of 24 the headaches have been more regular in their appearance, but she says that they only began to occur with "devastating regularity" after the birth of her first child in 1928. During her two pregnancies she had no headaches, was never sick, and felt extremely well.

She occasionally gets similar but less severe headaches during the intermenstrual period if subjected to undue strain and after travelling by train or boat, or in any vehicle with much vibration.

Up to the time when she first gave me this history she had tried the usual analgesics, such as aspirin and phenacetin, and had found that, though they might delay the onset of the headache, they never checked its course or prevented its development. Luminal was no more effective. She herself was convinced that the condition had its roots somewhere in the reproductive system, and was not to be approached by drugs acting on the central nervous system only. In 1928 she had her eyes examined by an ophthalmologist, who found in them nothing to account for the headaches. Her teeth and throat are in good condition, and her blood pressure 100/70.

Influenced by the fact that the headaches disappeared during pregnancy, I suggested that she might try taking extract of placenta by mouth, and ordered grs. 2 of Armour's dried preparation of placenta daily. She took the tablets in rather a desultory fashion for a few days before her July period. Neither of us, however, felt particularly confident that they would have any effect, and it cannot be said that the treatment received a thorough trial; at all events, the headache appeared promptly on the appointed day, and the patient refused to swallow any more placenta. The appearance of Dr. Thomson's article, however, and of the statement in your issue of August 20th that treatment of this condition with emmenin was being tried in Canada, gave me grounds for urging her to continue the treatment. Encouraged by the discovery that she had an authentic and recognised disease she embraced the remedy with fresh enthusiasm, and I took the opportunity to double the dose. The result, on the occasion of her August period, was remarkably successful; the onset of menstruation was delayed for a day or two, but the headache failed to develop, and she felt unusually well. How far a psychological basis explains this relief it is difficult to say, but further treatment along the same lines will doubtless determine. She is now prepared to take grs. 4 of the dried preparation daily throughout the intermenstrual period, and I should be glad to know whether there are any objections to this dosage.

In view of the X ray findings in 17 out of Dr. Thomson's 25 cases, a stereoscopic radiogram was taken of the region of the sella turcica, but no evidence was found of ossification of the interclinoid ligaments. It would be interesting to know, in terms of Dr. Thomson's theory of the cause of the pain, what is responsible for the sensation of movement inside the head felt by the patient just before the pain begins to abate. It scarcely seems possible that the pituitary, having remained for some time swollen and compressed against an abnormally complete dural roof to the sella turcica, begins to subside with such abruptness that the patient can distinguish the very moment at which, so to speak, the ebb sets in.—I am, Sir, yours faithfully,

MARGARET N. JACKSON.

Castelnau Gardens, S.W., Sept. 1st, 1932

"SAPRÆMIC" GLYCOSURIA

To the Editor of THE LANCET

SIR,—Temporary glycosuria is not uncommon; temporary hyperglycæmic glycosuria is much less common. One of the causes is a depression in the power of storing sugar due to an infection; this has been termed "sapræmic" glycosuria. A typical case is one in which the patient has multiple boils; sugar is found in the urine, but after the boils have healed the sugar disappears from the urine and the patient appears to possess the average capacity to utilise carbohydrate. I have had little opportunity of investigating such cases five or more years after the attack, but frequently patients who are suffering from diabetes mellitus tell me that they had "a touch of sugar some years ago." The object of this letter is twofold: to learn the result of investigation of these cases of temporary glycosuria, and also to ask practitioners who have happened to see these cases to send them to a hospital for the necessary investigation, and then to publish their cases to permit us to learn whether there is such a condition as "sapræmic" glycosuria, or whether it is not really a temporary exacerbation in early mild diabetes induced by the toxins of the infection.

I am, Sir, yours faithfully,

London, W., Sept. 3rd, 1932. O. LEYTON.

THE ÆTIOLOGY OF GOITRE

To the Editor of THE LANCET

SIR,—An annotation in your issue of August 20th (p. 408) gives me the opportunity for a few remarks on the goitre-producing qualities of the cabbage diet of the Carpathian highlanders in Ruthenia, a part of the Czechoslovak Republic, where on the basis of Colonel R. McCarrison's experiments I studied the occurrence of goitre. Goitre occurs endemically in parts of these highlands, in some of the bad centres there are cretins and cases of myxœdema; cretins were found not only amongst the Ruthenians but also amongst the Jews living in the same villages. The worst goitre centres are found in villages where during the colder months of the year more than two-thirds of the population live to a great extent on cabbage, with addition of potatoes, maize bread, and oats, and the villagers, apart from those engaged in lumber work, live an unhealthy life in dark unventilated huts. The quantities of cabbage consumed are not small, a family of five members consuming daily about 2½ kilos; the very poor families may have cabbage nearly daily—three to four times weekly is the rule. Cabbage is used as a store food, pickled for from two to three weeks. Generally the pickling begins about the middle of October, with some early cabbage at the end of September; a family of eight members may pickle about 500 kilos. This pickled cabbage, stored in barrels, is a very important part of the diet during the months October to December.

The ætiology of goitre is manifold, and we do not seek in the cabbage diet the one and only reason for goitre in the Ruthenian highlands, yet our observations, made quite independently of Colonel McCarrison, bear striking resemblance to his. The following Table gives a few figures:—

Occurrence of Goitre amongst Children of all Ages from 6 to 14 Years from all Villages

—	Cases	Without goitre and percentage.	Slight enlargement and percentage.	Medium enlargement and percentage.	Excessive enlargement and percentage.
Boys	*294*	*71 (24·1)*	*149 (50·7)*	*56 (19·0)*	*18 (6·2)*
Girls	245	65 (*26·5*)	113 (46·1)	44 (18·0)	23 (*9·4*)
Occurrence of Goitre amongst Children from Three Villages with Excessive Cabbage Diet					
Boys	161	16 (10·0)	87 (54·0)	44 (27·3)	14 (8·7)
Girls	114	9 (*7·9*)	64 (56·1)	23 (20·2)	18 (*15·8*)

The italicised figures show the marked differences.

In this table the well-known sex difference in the occurrence of goitre is distinctly marked; the percentage of cases without goitre out of the whole group of villages is much higher than the percentage from the three villages with excessive cabbage diet, while the percentage of cases with excessive goitre amongst the girls of the selected group is nearly twice as high as the percentage of the whole group. Following McCarrison, we put forward the view that the high incidence of goitre amongst the Carpathian highlanders is due to excessive cabbage diet during the winter months.

I am, Sir, yours faithfully,

Prof. V. SUK, M.D., Ph.D.

Brno, Masaryk University, Anthropological Institute, Czechoslovakia, August 27th, 1932.

THE SERVICES

Attendance on Officers' Families

COMPLAINT has recently been made that wives and families of military officers are left, by the new edition of the R.A.M.C. Regulations, just as they were before—only entitled to medical attendance by officers of that corps provided their lodgings are within a mile of the military hospital or the centre of the military station; and it has been proposed that the War Office should remove this limitation, as officers' families are now less able than formerly to pay the fees of practitioners in whose neighbourhood they may be settled. We were not told, of course, how many additional R.A.M.C. officers would then be required, nor how they are to be obtained, the strength of the corps being already 18 per cent. below establishment, for more medical officers would certainly be required, at least in the larger stations. The very considerable total of work done by the executive ranks of the corps is only made possible by collecting the patients for them in medical inspection rooms, so that time is not wasted in mere travelling, with clerks and orderlies to give help, and a hospital in the background to take charge of serious cases. The care of officers' families, in their widely scattered quarters, is a serious consideration to medical officers without the time-saving car that facilitates civil family practice.

ROYAL NAVAL MEDICAL SERVICE

Surg. Comdr. W. H. A. Sinclair-Loutit is placed on the Retd. List.

Surg. Lt.-Comdr. P. J. A. (The) O'Rourke to *Harebell*.

Surg. Lts. E. R. P. Williams to Portland Hospital; F. W. Besley to *Dorsetshire*; W. D. M. Sim to *Courageous*; R. J. Corbett to *Tamar*, and for duties in dockyard; W. M. Greer transferred to permanent list; J. J. Cusack to *Vernon*; F. G. V. Scovell to *Royal Sovereign*; and L. G. Yendoll to *Victory*, and to *Hawkins* (on commng.).

ROYAL NAVAL VOLUNTEER RESERVE

Payr. Lt. C. G. Batty-Smith, M.A., M.R.C.S., transferred to Medical Branch as Surg. Lt.

Proby. Surg. Sub-Lt. G. F. Jones to *Victory*, for Haslar Hospital.

ROYAL ARMY MEDICAL CORPS

Lt.-Col. S. E. Lewis retires on retd. pay.

Maj. H. H. Blake to be Lt.-Col.

Maj. J. La F. Lauder, half-pay list, retires, receiving a gratuity.

Lt. (on prob.) R. V. Wright is secd. under the provisions of Art. 213, Royal Warrant for Pay and Promotion, 1931.

Lt. (on prob.) J. V. Quinn resigns his commn.

MILITIA

Maj. C. M. Page retires on attaining the age limit and is granted the rank of Lt.-Col.

TERRITORIAL ARMY

Lt.-Col. J. V. Bates to be Bt. Col.

RESERVE OF OFFICERS. REGIMENTAL LIST

Lt.-Col. and Bt. Col. J. V. Bates, from Active List, to be Lt.-Col. and Bt. Col.

ROYAL AIR FORCE

RESERVE OF AIR FORCE OFFICERS

G. Dunderdale is granted a commission in Class DD as a Flight Lieutenant.

INDIAN MEDICAL SERVICE

Majs. to be Lt.-Cols.: R. Sweet, J. R. D. Webb, F. Phelan, A. C. Macrae, and N. C. Kapur.

Lt. (on prob.) to be Capt. (on prob.): H. D. R. Zschperel.

The undermentioned Capts. (prov.) are confirmed in rank: J. H. Boultbee, P. L. O'Neill, H. S. Smithwick, and H. J. Curran.

The probationary appts. of the undermentioned are confirmed: To be Capts.: Gopal Das Malhoutra, Bantwal Panduranga Baliga, and Raghubansa Kishore Tandon, from I.M.S. (T.C.).

The undermentioned appts. are made: To be Capt. (on prob.): G. R. M. Apsey. To be Lts. (on prob.): W. H. G. Reed, T. E. Palmer, W. J. Poole, and C. J. H. Brink.

PUBLIC HEALTH SERVICES

London School-children

STUDY of the report for 1931 of Sir Frederick Menzies, as school medical officer for the county of London, indicates that the percentage of children referred for treatment (excluding dental caries) has fallen from 38 in 1911 to 18·5 in 1931; that the percentage of children referred for treatment of defects who were found satisfactory on reinspection has risen during the same period from 42·5 to 81·6; that the percentage found unclean at routine medical examinations has fallen from 9·8 to 0·5. The heaviest burden the school medical service has to bear is stated to be the poor condition of the children's teeth. At two of the residential homes transferred to the council's jurisdiction from former poor-law authorities, arrangements have been made for supervision of the children's teeth by dental surgeons; in all the other transferred homes some system of dental inspection was in existence. The dietary at residential institutions has also undergone reform. The council have drawn up a new diet sheet, presented in the form of a table of foods for each separate meal of the day, the choice of menu on any one day being left to the school authorities; this makes considerable variety possible, and authorities are particularly advised to avoid serving one specially dull item on the same day each week. A daily fruit ration is included in the diet. "In view of the fact," the report states, "that apples are our best medicofuge and have the property of leaving the mouth in a clean and wholesome state, the fruit ration is prescribed in the form of a definite amount of apple to be taken every day as the last item of food." Provision for open-air education includes nine day schools for non-tuberculous children, with accommodation for 1648 pupils, and six day schools for tuberculous children, with accommodation for 515 pupils; there are also five convalescent camp schools accommodating 484 children at a time for short periods, and 200 open-air classes in playgrounds and parks. During the year the experiment was made of taking children normally attending day schools for the mentally defective to a residential camp school. In June 25 boys went to the school, and in September 25 girls. The results were highly successful, the children appearing to benefit both physically and mentally. Dr. E. J. Boome, who reported on the scheme, thought that the advantage of it lay partly in the fact that it was confined to mentally subnormal children; probably if they had been sent to ordinary residential schools the results would not have been so good, owing to their sense of inferiority when with comrades of normal intelligence. In advising open-air classes for children selected on medical grounds a distinction is drawn between the bronchitic and the rheumatic type of child. Experience has shown that the bronchitic child thrives on open-air treatment of the sanatorium type, and the more exposure he gets the better he is, while the rheumatic child cannot stand such treatment and needs warmth and coddling. The report deals also with the inspection in higher education institutions, following up institutional care of children under 3 years of age, chronic invalidity, employment of school-children, stammering, the council's rheumatism and personal hygienic schemes, school journeys, nursery schools, child guidance, blind and deaf children, defective children, and infectious disease in schools. In all these departments the work of the school medical service is of public utility, and the money spent upon it in the nature of an insurance premium or sinking fund on a redeemable debt. We learn that during the latter part of the year any economies which could be made without impairing efficiency were effected. The service itself makes for economy in the long run.

Out-patient Clinics at Mental Hospitals

The Kent county mental hospital at Barming Heath was one of those which had established an out-patient clinic before the Mental Treatment Act gave statutory encouragement. This clinic, in common with most of its fellows, has been much appreciated by local practitioners, by relatives, and by patients. During the year 1931 treatment was sought by 37 new cases, many of them coming from a considerable distance, and most of them suffering from obvious mental disorder. Certification was advised for 11, 4 were admitted as voluntary patients, and 2 were referred to the mental deficiency authority. Of the 37, 15 were considered to have recovered before the end of the year. One of the integral factors in these out-patients' clinics is the social worker, who can visit the patients' homes, interview relatives and friends, and obtain a much-needed history to lay before the doctor, as well as interesting herself in the many personal problems of occupation and home that are not strictly medical and have yet such a wide influence on the mental state of the patient. At present the clinic at Maidstone is without this help, but the need is becoming more and more apparent. A similar clinic has been started in connexion with the Chartham Downs mental hospital at the Kent and Canterbury mental hospital, and is proving increasingly useful. The City of Leicester mental hospital also holds a successful weekly out-patient clinic where 112 attendances were recorded during 1931. Of these, 31 were recommended by local practitioners and 15 were admitted as voluntary patients to the mental hospital. This aspect of the work emphasised the need for a reception block; if out-patients are to be encouraged to enter the hospital when their condition requires it, they must be provided with some more attractive accommodation than a mixed ward. Other uses for the out-patient clinic are exemplified by the two patients who reported there while on trial-leave from the hospital, and two more who attended for antisyphilitic treatment after their discharge. Leicester is happy in having the services of a mental welfare worker.

Confidential Investigations of Maternal Deaths

In a memorandum (164/MCW) to maternal and child welfare authorities the Ministry of Health commends the proposal that the local inquiries into maternal deaths made by the Departmental Committee on Maternal Mortality and Morbidity should not be allowed to lapse, but should be continued on similar though less detailed lines. Discussions of fatal cases between medical officers of health and practitioners are held to have enabled the former to estimate the adequacy and elasticity of the local organisation for maternal welfare, and the inquiries are believed to have also a direct educational value. A new and simpler report form has been drafted, with space for an account of antenatal care and for a brief description of the labour and puerperium, and comments are invited on any subjects which have a bearing on the case. It is desired that deaths following abortion and deaths primarily due to intercurrent disease should be included among those investigated. As the inquiry is solely for scientific and public health purposes, the information obtained is to be regarded as strictly confidential.

Disposal of Condemned Food at a Port

At the port of Manchester the vigilance of the medical officer of health kept off the market over 125 tons of imported food which were found defective and condemned. The history of a large consignment of tinned fruit illustrates the well-worn maxim that sanitation pays, while it also indicates the difficulties that arise in port sanitary work. The fruit, which weighed about 60 tons, came from the Pacific, and was stowed near the boilers in two holds whose ventilation should have kept the temperature down, but bad weather hindered ventilation, and on arrival in December a large number of the tins were found blown (that is bulged) and containing hydrogen; some were even burst. Others, outwardly sound, were found on opening to have their contents darkened and to contain tin in amounts varying from 0·2 to 2·7 grains to the pound, suggesting prolonged heating to 149° F. at least. Which of the tins were thus decomposed could only be decided after individual opening and so the whole consignment had to be condemned. As the consignees objected, this involved two attendances of a magistrate, who confirmed the decision of the medical officer. Claim was then made for return of customs duties already paid, so the tins had to be destroyed under the supervision of both customs and port sanitary authority. Destruction proved difficult. The tins could not be burned, and to dump them at sea was expensive. In this difficulty the Ship Canal Company came to the rescue, allowing the whole to be buried in their sludge dump, where the tins were at last sunk out of sight in May, and got rid of. Want of sufficient ventilation in the vessel's holds thus gave six months of trouble to Manchester officials. As it also caused loss to owners and underwriters, we may expect improvement after so clear a demonstration that sanitation saves money.

MONAGHAN COUNTY HOSPITAL.—This institution, housed in what was formerly a jail, is to be replaced by a modern building, built largely out of sweepstake funds.

ANNUAL REPORTS OF MEDICAL OFFICERS OF HEALTH

THE following are 1931 statistics of two county boroughs, two boroughs, and one urban district.

Name of district and estimated (R.-G.) mid-year population.	Birth-rate.	Death-rates per 1000 of the population.					Death-rates per 1000 live births.		
		All causes.	Tuberculosis.	Cancer.	Respiratory diseases with influenza.	Heart disease.	Infant and neonatal mortality.	Young child (1–5 yr.) mortality.	Maternal mortality in childbirth.
Walsall .. (104,100)	19·5	11·3	1·03	1·15	2·0	2·2	74/35	24	2 9
West Bromwich (82,160)	20·7	12·1	0·80	1·28	2·8	2·0	86/31	38	4 7
Colchester .. (45,090)	15 0	11·5	1·06	1·66	1·3	2·1	48/—	26	0 0
Stafford .. (29,430)	11·8	11·5	0·71	1·18	1·9	2·0	63/34	29	5 7
Weston-super-Mare .. (27,310)	9·8	13·2	0·58	1·83	1·6	2·6	52/—	—	1 05

Registered stillbirths per 100 live births: Walsall 3·8, West Bromwich 4·5, Colchester 3·5, Stafford 5·2, Weston-super-Mare 4·5.

Walsall

Dr. J. A. M. Clark states that the borough extension on April 1st, 1931, added an area of 1297 acres and a population of 820 persons, and increased the number of houses lacking a piped supply of water and sewerage provision. The water from seven wells was analysed during the year, and five showed evidence of sewage pollution, while two were unsatisfactory. Of three springs examined, the water of one showed sewage pollution, and of another was unsatisfactory. As it is impracticable at present to supply the houses concerned from the public water-supply, the users of the water have been advised to boil it before use. Much attention has been given to checking the pollution of rivers and streams during the year. Two considerable sewerage schemes are in hand. There are over 4000 water-closets which have to be flushed by bucket. Rapid progress is being made in the substitution of bins for ashpits. Progress is being made with slum clearance, and a scheme covering 176 dwellings with a population of 937 is in hand.

There are now four hospitals under the control of the council, managed by three entirely separate committees. Dr. Clark indicates that effective coördination is lacking, and that his duties as principal medical officer to the public assistance committee are nominal only. The Manor Hospital (ex-poor-law) remains under the control of the public assistance committee. The admissions have increased from 1514 in 1929 to 2402 in 1931. The surgical work has increased tenfold in the last three years, and the proportion of acute work becomes continually greater. The confinements in the maternity department numbered 136 as compared with 83 in the previous year. The maternity ward has been transferred to the old nurses' home, but the department still lacks space, and the labour room is too small. The isolation hospital, which was opened in April, 1930, has experienced another very full year, and needs the addition of another ward of 25 to 35 beds. A further proposal to erect a block of 24 beds for tuberculosis awaits the approval of the Ministry.

Dr. Clark has much to say in praise of the new specially built infant welfare centre, situated in the middle of one of the housing estates, which was opened by the mayoress in June. The maternity and child welfare hospital has ten beds, and the demand far exceeds the accommodation provided. Out of the 150 infant deaths, 47 were recorded as due to prematurity, and Dr. Clark is at a loss to account for this high proportion, seeing that the rate for stillbirths is comparatively low. The first antenatal clinic was established in 1928, and the work has steadily increased. The first noticeable decline in the premature death-rate occurred in 1930. During 1931 the total births were 2034, and the new cases attending the four antenatal clinics numbered 619. No adequate provision has been made for the dental treatment of the mothers. The immunisation of children against diphtheria is being continued at the schools and welfare centres; 691 children were treated for the first time, and 921 who had been previously tested were retested. Of 573 children immunised during previous years, 76 again reacted to the test, whilst in 497 immunity had been established. During the past four years 7302 children and adults have been dealt with and 4900 immunised.

During the year a Salvation Army hostel for men was opened by the mayor. The building, formerly offices and workrooms, has been adapted for its purpose with admirable results, and provides accommodation for 120. The average number of beds occupied nightly is 107.

West Bromwich

Dr. J. Yule reports that the dovetailing of the new functions, taken over by the department under the Local Government Act, 1929, into previously existing duties has made good progress. Hallam Hospital (ex-poor-law) has rendered excellent service during its first complete year as a municipal hospital, not only to the borough but to neighbouring authorities. It has a complete specialist visiting staff, and about half of the 474 beds are used by West Bromwich. There were no deaths from scarlet fever or diphtheria during the year. Dr. Yule complains of the great delay in the notification of tuberculosis. During 1931 the new cases examined at the dispensary numbered 175 and the new contacts 89. The efficiency of the tuberculosis department has been greatly enhanced by the increasing use of the up-to-date X ray department at Hallam Hospital, and the services of the radiologist, Dr. G. E. Dyas. Good results are claimed for the ultra-violet light treatment, the plant for which is located at the dispensary. A complete orthopædic scheme with a clinic is one of the needs stressed.

There are six antenatal clinics, which were attended by 328 new cases. The total births numbered 1698. In addition to the clinics mentioned, antenatal and postnatal clinics, conducted at the Hallam Hospital by Mr. J. S. M. Connell, F.R.C.S., the visiting gynæcologist, now form an invaluable and integral part of the maternity scheme. Mental defectives are sent to Great Barr Park colony, which is under the joint control of Walsall and West Bromwich, but there is serious difficulty in obtaining admission for low grade cases to this colony. It is hoped that the sewerage of the borough will be satisfactory for a considerable period, after the expenditure of £37,000 for new sewers at Perry Bar, and of £112,000 on the outfall works. This new work will occupy about three years. Smoke abatement is not helped by the fact that the corporation "possess chimney stacks which are not beyond reproach."

Colchester

Dr. W. F. Corfield states that the isolation hospital was of great service to surrounding districts as well as the borough. The cases of diphtheria admitted were 78, and the number of deaths was unusually large—viz., 9, giving a case-fatality of 11·5 per cent. All the deaths were due to delay in the administration of antitoxin. Three cases died on the day of admission, and in two tracheotomy was performed, but both died some days after from heart failure. There were nine notifications of dysentery, one from military quarters, four from the Eastern Counties Institution, and four from military families living in the town. No origin could be found for the military case in a sergeant's child, but the mother and two other children were found to be harbouring dysentery bacilli, and also a child in the next bed in the military hospital. All the last-named cases recovered.

Mr. Ronald Reid, F.R.C.S., has been appointed consulting surgeon to the isolation hospital. The question of admitting cases from Harwich borough and Clacton U.D., the only two districts in the Tendring peninsula which do not at present use the hospital, is under consideration, and also the proposal the the Colchester small-pox hospital should receive cases from the whole of the north of the county. At the time of writing the new maternity home was almost ready for its first patient. The staff will consist of a matron, one sister and two nurses, all qualified midwives. New patients at the antenatal clinic numbered 103, the total births being 732. It is expected that the antenatal clinic will be more appreciated when it works in direct connexion with the new maternity home.

Stafford

Dr. J. T. Macnab states that the difficulty of housing the large family with the small income is still urgent, and that the low-rented pre-war house, which often has to be demolished in an improvement scheme, is in great demand. The owners of two houses appealed to the Ministry against the charges made by the corporation for renovation work done in default. The decision of the Ministry was in favour of the corporation, the appellants having to bear the cost of the inquiry. During the first half of 1932, the Stone-road site will be completed by the erection of 52 houses, and the Stafford common committee have been approached with regard to a site on the new common for the erection of 200 additional houses. In view of the fall in the birth-rate this provision may be sufficient for present needs, but there are still a number of very badly housed families, whose cases have not been met by any of the subsidised houses. During the year the Bradford system of controlled tipping has been introduced, and its successful working has enabled the replacement of the worn-out destructors to be postponed. Recent inspections show that there are 5735 water closets with flushing cisterns and 1678 waste-water closets. The latter give rise to a great deal of trouble from the occurrence of stoppages, but only 19 were converted to water-closets with flushing cisterns during the year.

There are in the borough 112 registered milk retailers for 6807 houses, an average of one retailer for 60 houses. Dr. Macnab finds that persons who have failed at other jobs and are often far from models of cleanliness endeavour to retrieve their fortunes by starting a small milk round. Every small street is visited by several milkmen, and he thinks that with better organisation all milk could be raised at least to Grade A standard without increase in cost to the public or fall in price to the producer. At least one of the retailers of Grade A milk visits the town only on alternate days.

There is no municipal maternity home, and Dr. Macnab would like to see an annex to the infirmary provided for the purpose. The new cases at the antenatal clinic number 36, the total births being 348. Sterilised maternity outfits are supplied at cost price (3*s.* and 6*s.* 3*d.*), but up to the present there is little demand for them.

Weston-super-Mare

Dr. A. E. Remmett Weaver reports that the maternity and child welfare scheme is carried on by a voluntary association which receives an annual contribution of £135, and the help of the assistant health visitor at all sessions. The antenatal clinic was attended by 58 new cases, the total births being 267. There is no maternity home or hospital in the district. At a meeting of the local medical profession it was decided that if the voluntary hospital were to admit antenatal cases for observation and complicated maternity cases for confinement, and if septic maternity cases were received in the isolation hsopital, no further institutional accommodation for maternity cases in Weston-super-Mare would be required. The voluntary hospital has agreed to accept these cases without charge until they have had experience of the effect of such admissions on their finances. Maternal mortality in Weston is a good illustration of the fact that one cannot judge the maternal mortality of a district with a small population for single years. During the ten years 1921–30 there were no maternal deaths from puerperal sepsis, and only nine from other puerperal causes, giving a total maternal mortality of 2·84 per thousand live births, as compared with 4·08 for England and Wales. During the ten years 1922–31, however, the maternal mortality in Weston was 3·92 as compared with 4·10 for England and Wales.

The inadequacy of the isolation hospital (18 beds) has been under consideration since the end of the war. Plans and estimates were submitted to the county council, but the health committee deferred consideration of the scheme.

PORT SANITARY AUTHORITY

Hull and Goole

IN his first report for 1931 to the port sanitary authority, Dr. Nicolas Gebbie states that 7094 ships from abroad arrived in the area, 5869 coastwise; 373 were inspected by a medical officer, 6939 by sanitary inspectors, a certain number coming in for double inspection. The total expenditure of the authority was £5150 of which £2114 was chargeable to the rates, four-fifths to Hull, one-fifth to Goole. The main inward trade was in provisions and oil, both vegetable and mineral. Water-supply for shipping is from deep wells and taken from water boats or hydrants on the dock-side; the 13 water boats were frequently inspected. The water storage tanks of 57 vessels required cleaning; of 22 samples of water from ships' tanks, only one had definite bacteriological (but undisclosed) evidence of contamination. No important infectious disease prevalence occurred. Of 53 cases of venereal disease discovered through inquiry on arrival, 41 attended the clinic in Mill-street. Rats totalling 8238 were destroyed; 6928 (all black) on ships, 1310 ashore (two-thirds brown). As to crew spaces, defects of original construction existed on 4 per cent. of the British, on 20 per cent. of the foreign ships examined, 230 (nationality unstated) had no water-supply to the crews' water-closets and 3 had no w.c. for them at all; defects by wear and tear were 912, slightly more numerous on foreign ships; nuisances by dirt and vermin were more prevalent on British ships, verminous bunks were "fairly numerous," 106; 1403 dirty and old beds were burned on board vessels. The 1403 beds were the straw-filled beds issued to seamen in many "tramps," and are constantly burned at end of voyages as the men leave. It is not stated whether all the 1403 came from British ships. No infectious cases were reported from any of the 863 canal boats. In the course of food inspection, over five million packages were examined, and 122 tons of fruit, 31 tons of shell-fish, 3 tons of wheat, and 1 cwt. of meat were declared unsound. Total aliens arriving at the port were 3627, none were rejected (certificated), and the standard of cleanliness of transmigrants is generally high.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED AUGUST 27TH, 1932

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 13 (last week 17); scarlet fever, 1038; diphtheria, 639; enteric fever, 53; acute pneumonia (primary or influenzal), 380; puerperal fever, 34; puerperal pyrexia, 93; cerebro-spinal fever, 24; acute poliomyelitis, 16; acute polio-encephalitis, 2; encephalitis lethargica, 10; dysentery, 15; ophthalmia neonatorum, 90. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on August 30th–31st was as follows:—Small-pox 22 under treatment (last week 21 and 3 under observation); scarlet fever, 1087; diphtheria, 1231; enteric fever, 12; measles, 442; whooping-cough, 422; puerperal fever, 21 (plus 8 babies); encephalitis lethargica, 229; poliomyelitis, 3; "other diseases," 112. At St. Margaret's Hospital there were 16 babies (plus 7 mothers) with ophthalmia neonatorum.

Deaths.—In 117 great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 17 (2) from measles, 3 (0) from scarlet fever, 23 (6) from whooping-cough, 16 (1) from diphtheria, 77 (24) from diarrhœa and enteritis under two years, and 12 (1) from influenza. The figures in parentheses are those for London itself.

The deaths from diarrhœa were 32 more than in the previous week and were widely distributed over the country, the highest figures being Manchester 6, St. Helens 5, Leeds 4, Liverpool and Nottingham each 3. There has now been a clear quarter without the report of a death from small-pox. The fatal case of enteric fever occurred at Barking. Three of the deaths from measles were reported from Liverpool, 2 each from Gateshead, Newcastle-on-Tyne, Wigan, and Birmingham. Leeds and Sheffield each reported 3 deaths from whooping-cough. Diphtheria claimed 3 victims at Liverpool, 2 each at Croydon and Manchester.

The number of stillbirths notified during the week was 246 (corresponding to a rate of 36 per 1000 total births), including 29 in London.

MEDICAL NEWS

Royal Faculty of Physicians and Surgeons, Glasgow

At a recent meeting of the Faculty the following were admitted to the Fellowship: Thomas Symington Macaulay and Gopal Das Malhoutra.

Paddington Medical Society

A meeting will be held on Sept. 13th at the Great Western Royal Hotel, Paddington, at 9 P.M., when Dr. Frederick Dillon will read a paper on early signs of mental disorder and some practical difficulties connected therewith from the point of view of the general practitioner.

Nordrach-on-Dee Sanatorium

This sanatorium, at Banchory, is in liquidation, and the property is in the market. The site was chosen in 1899 by a committee of professors of medicine of the four Scottish universities, and this was the first specially built sanatorium in Scotland. It stands in 25 acres of grounds in a sheltered clearing among the pines, 400 feet above sea-level.

St. Mary's Hospital Medical School

The week-end post-graduate course will be held this year from Sept. 30th to Oct. 2nd. The morning session each day extends from 10.15 to 12.45, during which three lectures will be given. On each of the afternoons of Sept. 30th and Oct. 1st two lectures will be held between 2.15 and 4 P.M. The morning lectures on Sept. 30th will be on phlebitis, backache in women, and chronic affections of the appendix and gall-bladder, by Mr. A. Dickson Wright, Mr. Aleck Bourne, and Sir William Willcox. In the afternoon Mr. Leslie Williams will speak on anæsthesia and analgesia in obstetrics, and Dr. T. C. Hunt on some recent methods of treatment. On Oct. 1st Mr. Herbert Tilley will speak on purulent nasal discharges, Dr. Robert Hutchison on pink disease, and Dr. Reginald Miller on school problems in private practice, in the morning; while in the afternoon Dr. S. Vere Pearson will discuss modern developments in sanatorium treatment, and Mr. T. G. Stevens the causation and treatment of maternal injuries in childbirth. Sunday morning will be devoted to lectures on prostatic problems, by Mr. R. M. Handfield-Jones; the treatment of *B. coli* infections by a ketogenic diet, by Dr. C. M. Wilson; and some controversial points about appendicitis, by Mr. V. Zachary Cope. These meetings are open to all medical practitioners, without fee.

The annual dinner of past and present students will be held on Friday, Sept. 30th, at 7.30 P.M., at the Trocadero Restaurant. Sir Joseph Skevington will be in the chair.

King's College Hospital Medical School

On Oct. 1st, instead of the usual opening ceremony and inaugural address, an "intensive post-graduate course" will be held. Between 2 and 5.30 P.M. on that day a series of short lectures and demonstrations will be given, with half an hour's interval for tea at 4.30. The provisional programme is as follows: 2 P.M., Treatment of Coli Bacilluria and Pyelitis, by Mr. Yates Bell; 2.30, Asthma and Desensitisation, by Dr. J. L. Livingstone; 3.15, Practical Points in Gynæcological Cases, by Mr. W. Gilliatt; 3.45, lecture-demonstration, by Mr. Cecil Wakeley and Mr. H. L. C. Wood, on Injection Treatment of Varicose Veins; 5.0, Felton's Antipneumococcal Serum, by Dr. Douglas Firth. During the afternoon a demonstration of blood transfusion methods will be held in the pathological laboratory, and, between 3 and 4, Mr. John Everidge will give a lecture-demonstration in an operating theatre on the electro-coagulation treatment of enlarged prostate.

The post-graduate lectures, held last year at 9 P.M. on Thursdays, will be resumed this session, the first being on Oct. 13th, when Dr. Wilfred Sheldon will speak on Nervous Habits in Children. Subsequent lectures will be announced in our Medical Diary. These lectures are free to medical practitioners and to final year students of King's College Hospital.

The annual dinner of past and present students will be held on Oct. 1st, at 7.30 P.M., in the Connaught Rooms. Dr. Godfrey de Bec Turtle will preside.

Fellowship of Medicine and Post-Graduate Medical Association.

Two afternoon courses will take place from Sept. 12th to 24th: at the Infants Hospital in diseases of infants, and at the Royal Eye Hospital in ophthalmology. Other courses during September and October include medicine, surgery, and the specialties at the Westminster Hospital (Sept. 19th to Oct. 1st), Metropolitan Hospital (Oct. 3rd to 15th), and the Miller Hospital (Oct. 17th to 29th): dermatology at St. John's Hospital (Oct. 3rd to 29th); oto-rhino-laryngology at the Central London Throat, Nose, and Ear Hospital (Oct. 3rd to 29th); proctology at the Gordon Hospital (Oct. 3rd to 8th): diseases of the chest at the Brompton Hospital (week-end, Oct. 8th and 9th). A series of lectures on renal disease will be given on Tuesday afternoons at the house of the Medical Society of London, at 4 P.M., for Members. A week-end course in rheumatism will be given at Bath on Oct. 1st and 2nd. A course of evening lecture-demonstrations on physical medicine will be given at the London Light Clinic on Mondays and Wednesdays from Oct. 3rd to 27th, and an evening course of demonstrations on rheumatism will be held by the British Red Cross Clinic on Tuesdays and Thursdays from Nov. 8th to 25th. A week-end course in obstetrics will be given at the City of London Maternity Hospital on Oct. 29th and 30th. Further particulars may be obtained from the secretary of the Fellowship, 1, Wimpole-street, London, W.

Appointments

Certifying Surgeons under the Factory and Workshop Acts: SIMPSON, J. B. (Newmilns District, Ayr).

London County Council: CARVER, JAMES, M.B. N.U.I., F.R.C.S. Eng., medical superintendent, St. George-in-the-East Hospital, promoted medical superintendent, St. Mary Abbots Hospital, in place of Dr. A. Remington Hobbs, deceased.

Vacancies

For further information refer to the advertisement columns

Albert Dock Hospital, Connaught-road, E.—Res. M.O. At rate of £110.

All Saints' Hospital, Austral-street, West-square, S.E.—Res. H.S. At rate of £100–£150. Also Hon. Anæsthetist.

Bangor, Caernarvonshire and Anglesey Infirmary.—Jun. H.S. £100.

[illegible]—Res. M.O. At rate of £150.

[illegible] O. At rate of £100.

[illegible]—H.S. At rate of £130.

[illegible] t. Ophth. H.S.

Chester, East Lancashire Tuberculosis Colony, Barrowmore Hall, Gt. Barrow.—H.P. At rate of £100.

Children's Hospital, Hampstead, College-crescent, Swiss Cottage, N.W.—Res. M.O. At rate of £100.

Colchester, Royal Eastern Counties' Institution, &c.—Res. Asst. M.O. £350.

Derby, Derbyshire C.C.—M.O. £600.

Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—Asst. Radiologist for X Ray Dept. £100. Also Hon. Clin. Assts.

Fareham, Hants, Knowle Mental Hospital.—Second Asst. M.O. £550.

Glasgow Eye Infirmary.—Res. Asst. H.S. £150. Also Anæsthetist. £100.

Gloucester, Gloucestershire Royal Infirmary, &c.—H.S. At rate of £150.

Halifax Royal Infirmary.—Third H.S. £150.

Hampstead General and N.W. London Hospital, Haverstock Hill, N.W.—Cas. Surg. O. for Out-patient Dept. At rate of £100.

Hospital for Sick Children, Great Ormond-street, W.C.—H.P. and H.S. Each at rate of £100.

Hospital for Women, Soho-square, W.—Res. M.O. At rate of £100.

Ipswich, East Suffolk and Ipswich Hospital.—H.S. £120.

Kendal, Westmorland County Hospital.—H.S. At rate of £200.

Leeds, Jewish Herzl Moser Hospital, Leopold-street.—R.M.O. £200.

Leeds University.—Part-time Lecturer. £400.

Leicester Royal Infirmary.—Two House Surgeoncies. Each £125.

Liverpool, Walton Hospital, Rice Lane.—2nd Sen. Asst. Res. M.O. £350.

London Lock Hospital, 91, Dean-street, W.—Surg. Reg. £100.

London Lock Hospital, 283, Harrow-road, W.—Res. M.O. At rate of £175.

National Hospital, Queen-square, W.C.—Hon. Dental Surgeon.

Newcastle General Hospital.—Part-time Surg. Reg. £250.

Newcastle-upon-Tyne Hospital for Sick Children.—H.P. Sen. and Jun. H.S. Each at rate of £100.

Oldham Royal Infirmary.—H.S. At rate of £175.

Oswestry, Shropshire Orthopædic Hospital, &c.—H.S. At rate of £200.

Portsmouth, Royal Hospital.—Sen. H.S. At rate of £175. Also H.P., Two H.S.'s and Cas. O. At rate of £130 and £100 respectively.

Princess Louise Kensington Hospital for Children, St. Quintin-avenue, W.—H.S. At rate of £75.

Queen's Hospital for Children, Hackney-road, E.—H.P. and Cas. O. Each at rate of £100. Also Ophthalmic Surgeon.

Royal Institute of Public Health, 23, Queen-square, W.C.—Asst. Bacteriologist.

Royal National Orthopædic Hospital, 234, Gt. Portland-street, W. H.S. At rate of £150.

St. Helens County Borough.—Asst. M.O.H. £500.

St. Helens Hospital.—H.S. £200.

St. John's Hospital, Lewisham, S.E.—Res. H.S. At rate of £100.

St. Leonards-on-Sea, Buchanan Hospital.—Sen. and Jun. H.S. At rate of £175 and £125 respectively.

Salford Royal Hospital.—Two H.S.'s to Special Depts. Each at rate of £125.

Scarborough Hospital and Dispensary.—Two H.S.'s. Each at rate of £175.

Sheffield Royal Infirmary.—Asst. Aural and Ophth. H.S. At rate of £100.

Southend-on-Sea General Hospital.—Hon. Physician to Electro-Therapeutic Dept. Also Res. H.P., H.S. and Cas O. Each at rate of £100.

Taunton, Taunton and Somerset Hospital.—H.S. At rate of £100.

Walsall General Hospital.—H.P. and Res. Asst. Pathologist. At rate of £150.

West Bromwich, Hallam Hospital.—Temporary Res. H.P. At rate of £200.

West Bromwich and District General Hospital.—Cas. H.S. £200.

West Ham County Borough.—Part-time Medical Practitioner for Maternity and Child Welfare Work. 1¼ gns. per session.

West London Hospital, Hammersmith-road, W.—H.P., Three H.S.'s, and Res. Anæsthetist. Each at rate of £100.

Westminster Hospital, S.W.—Medical Registrar. £150.

Wolverhampton, Royal Free Hospital.—H.S. for Ear, Throat, and Nose Dept. At rate of £100.

Worcester General Infirmary.—Pathologist. £400.

The Chief Inspector of Factories announces vacancies for Certifying Factory Surgeons at Westminster (County of London) and Westbury-on-Trym (County of Gloucester).

Births, Marriages, and Deaths

BIRTHS

THORNTON.—On August 29th, at "Lisnanagh," Forest Row, Sussex, the wife of G. Kennedy Thornton, M.B., of a son.

WHITE.—On Sept. 2nd, at Green Trees, Bassett, Southampton, the wife of Herbert Oakley White, M.R.C.S. Eng., L.R.C.P. Lond., of a son.

MARRIAGES

CORMACK—BARRY.—On Sept. 1st, at Holy Trinity Church, Ayr, Robert Cormack, F.R.C.S. Edin., of Ayr, to Margaret Euphans, daughter of Mr. and Mrs. Kenneth Wolfe Barry, of Chelsea, London.

GIBSON—ORR.—On August 31st, at St. Saviour's, Walton-place, S.W., Beale Hepburn Gibson, M.R.C.S. Eng., L.R.C.P. Lond., to Mary, daughter of Commander H. J. Orr, R.N., and Mrs. Orr.

SHERIDAN—SPRAWSON.—On August 13th, at Ootacamund, South India, Captain Arthur Manus Sheridan, M.B., Ch.B. Glasg., I.M.S., to Theodora, daughter of Major-General C. A. Sprawson, C.I.E., V.H.S., I.M.S., Surgeon-General with the Government of Madras.

DEATHS

BARRON.—On August 30th, suddenly, at Redlynch, Burnham, Somerset, Thomas Walter Barron, M.A., M.B. Camb., aged 81.

LOUGHNAN.—On Sept. 1st, at New Milton, Hants, Michael Loughnan, L.R.C.P.I. & L.M., L.R.C.S.I., formerly of Rathmullen, Co. Donegal, in his 85th year.

STOTT.—On August 31st, at St. Andrew's-place, Lewes, Hugh Stott, J.P., M.R.C.S., L.R.C.P., D.P.H., Medical Officer of Health for East Sussex, aged 74.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

further institutional accommodation for maternity cases in Weston-super-Mare would be required. The voluntary hospital has agreed to accept these cases without charge until they have had experience of the effect of such admissions on their finances. Maternal mortality in Weston is a good illustration of the fact that one cannot judge the maternal mortality of a district with a small population for single years. During the ten years 1921–30 there were no maternal deaths from puerperal sepsis, and only nine from other puerperal causes, giving a total maternal mortality of 2·84 per thousand live births, as compared with 4·08 for England and Wales. During the ten years 1922–31, however, the maternal mortality in Weston was 3·92 as compared with 4·10 for England and Wales.

The inadequacy of the isolation hospital (18 beds) has been under consideration since the end of the war. Plans and estimates were submitted to the county council, but the health committee deferred consideration of the scheme.

PORT SANITARY AUTHORITY

Hull and Goole

In his first report for 1931 to the port sanitary authority, Dr. Nicolas Gebbie states that 7094 ships from abroad arrived in the area, 5869 coastwise; 373 were inspected by a medical officer, 6939 by sanitary inspectors, a certain number coming in for double inspection. The total expenditure of the authority was £5150 of which £2114 was chargeable to the rates, four-fifths to Hull, one-fifth to Goole. The main inward trade was in provisions and oil, both vegetable and mineral. Water-supply for shipping is from deep wells and taken from water boats or hydrants on the dock-side; the 13 water boats were frequently inspected. The water storage tanks of 57 vessels required cleaning; of 22 samples of water from ships' tanks, only one had definite bacteriological (but undisclosed) evidence of contamination. No [illegible] occurred [illegible]ed, it is an essential quality of one who practises an art to transfer his mental experience into other minds through whatever medium he happens to use. Thus it may be worth inquiring in what way doctors who regard medicine as an art demonstrate this quality. If one considers the medium—whether poetry, music, architecture, painting—through which artists work in order to project their minds into the minds of others, it will be found that it always has something which we can call "pattern." Similarly, normal people, who do not come under medical care, may be said to have a fairly normal pattern in their lives; it may not be an exciting pattern, but it is a good enough one for them. People who come to consult doctors, on the other hand, are aware that their lives are in some way being upset. In so far as we deal with them scientifically we treat them as objects of rational diagnosis and of rational or empirical treatment; but when we get beyond this relatively simple sphere of management we automatically fall back upon our art. It is then upon the way in which *we* behave to them, not so much upon how *they* react, that the restoration of their physiological and psychological pattern depends; the patient's personality becomes our canvas. The pattern which we leave there will correspond to some extent upon the pattern already existing in our own minds. To give a concrete example: if a doctor believes that most indefinite human ills can be attributed to intestinal poisoning, we shall find in his patients people whose interest is to a large extent centred in the frequency of their motions and the odour and reactions of their fæces—not a pattern which we should choose for any life that was dear to us. Or again, if he believes that most indefinite ills are due to sexual causes, he is liable to produce in the minds of his patients an introspective sexual outlook on life, which he could certainly never choose to produce in a member of his own family. One may see patterns of all kinds in the lives of patients whose troubles are not due to

lethargica, 10; dysentery, 15; ophthalmia neonatorum, 90. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on August 30th–31st was as follows:—Small-pox 22 under treatment (last week 21 and 3 under observation); scarlet fever, 1087; diphtheria, 1231; enteric fever, 12; measles, 442; [illegible] puerperal fever, 21 (plus 8 babies); [illegible] 229; poliomyelitis, 3; "other d[illegible] Margaret's Hospital there were 16 babies (plus 7 mothers) with ophthalmia neonatorum.

Deaths.—In 117 great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 17 (2) from measles, 3 (0) from scarlet fever, 23 (6) from whooping-cough, 16 (1) from diphtheria, 77 (24) from diarrhœa and enteritis under two years, and 12 (1) from influenza. The figures in parentheses are those for London itself.

The deaths from diarrhœa were 32 more than in the previous week and were widely distributed over the country, the highest figures being Manchester 6, St. Helens 5, Leeds 4, Liverpool and Nottingham each 3. There has now been a clear quarter without the report of a death from small-pox. The fatal case of enteric fever occurred at Barking. Three of the deaths from measles were reported from Liverpool, 2 each from Gateshead, Newcastle-on-Tyne, Wigan, and Birmingham. Leeds and Sheffield each reported 3 deaths from whooping-cough. Diphtheria claimed 3 victims at Liverpool, 2 each at Croydon and Manchester.

The number of stillbirths notified during the week was 246 (corresponding to a rate of 36 per 1000 total births), including 29 in London.

MEDICAL NEWS

[illegible] applies himself to [illegible] patients, often with great success,

Royal Faculty [illegible] he is, he is *not* interested in what he [illegible]ther contemptuously calls the patient with nerves, unless he can persuade himself that there is a definite physical cause to which he can apply his energies. His simplest plan is to find a course of treatment which will satisfy his mind and that of his patients that *something* is being done for them; but, as we know too well, the benefit of every new departure is liable to cease when its effect on the patient's mind has worn off, and some new gesture is required. The man of action finds it difficult to treat successfully patients with "nerves," and to restore them to normal and active life.

THE AVOIDANCE OF MENTAL WARFARE BETWEEN DOCTOR AND PATIENT

The psychologists have done a great service in endeavouring to define the normal pattern of a man's or a woman's life—the various stages through which they pass, how they are at one stage tied to the mother, at another to the father, at another to the companion at school. While it is a matter of common sense to see how this man or that woman has been deprived of certain influences upon the pattern of their lives—e.g., the boy who has never been sent to school, or the only child who has never grown away from parental influences and never acquired initiative—it is much harder to trace these effects in the minds of neurotics, where the whole personality has got overlaid with quasi-physical symptoms, and tragic events have passed into the unconscious.

There is much scepticism upon the efficacy of any psychological methods among practitioners who are primarily men of action (or extraverts as some prefer to call them). While no practitioner can be expected to acquire the technique of unravelling intricate psychological threads, he should be able to acquire a sense of his patients' difficulties, of the spoiled patterns of their lives, and to try to help them. It is difficult to believe that any purely "nervous" state can be permanently helped by physical suggestion; symptoms can be temporarily ameliorated by sedative drugs, but, for example, as Dr. Crichton Miller has pointed out, hypnotics, while

King's College Hospital Medical School

On Oct. 1st, instead of the usual opening ceremony and inaugural address, an "intensive post-graduate course" will be held. Between 2 and 5.30 P.M. on that day a series of short lectures and demonstrations will be given, with half an hour's interval for tea at 4.30. The provisional programme is as follows: 2 P.M., Treatment of Coli Bacilluria and Pyelitis, by Mr. Yates Bell; 2.30, Asthma and Desensitisation, by Dr. J. L. Livingstone; 3.15, Practical Points in Gynæcological Cases, by Mr. W. Gilliatt; 3.45, lecture-demonstration, by Mr. Cecil Wakeley and Mr. H. L. C. Wood, on Injection Treatment of Varicose Veins; 5.0, Felton's Antipneumococcal Serum, by Dr. Douglas Firth. During the afternoon a demonstration of blood transfusion methods will be held in the pathological laboratory, and, between 3 and 4, Mr. John Everidge will give a lecture-demonstration in an operating theatre on the electrocoagulation treatment of enlarged prostate.

The post-graduate lectures, held last year at 9 P.M. on Thursdays, will be resumed this session, the first being on Oct. 13th, when Dr. Wilfred Sheldon will speak on Nervous Habits in Children. Subsequent lectures will be announced in our Medical Diary. These lectures are free to medical practitioners and to final year students of King's College Hospital.

The annual dinner of past and present students will be held on Oct. 1st, at 7.30 P.M., in the Connaught Rooms. Dr. Godfrey de Bec Turtle will preside.

Fellowship of Medicine and Post-Graduate Medical Association.

Two afternoon courses will take place from Sept. 12th to 24th: at the Infants Hospital in diseases of infants, and at the Royal Eye Hospital in ophthalmology. Other courses during September and October include medicine, surgery, and the specialties at the Westminster Hospital (Sept. 19th to Oct. 1st), Metropolitan Hospital (Oct. 3rd to 15th), and the Miller Hospital (Oct. 17th to 29th); dermatology at St. John's Hospital (Oct. 3rd to 29th); oto-rhino-laryngology at the Central London Throat, Nose, and Ear Hospital
by doctors, do not [illegible]ology at the Gordon Hospital
patients as do general practit[illegible]chest at the Brompton
among others, practitioners should [illegible]series of lectures
to elucidate certain points, but should never, [illegible] the
when asking the help of the psychological special[illegible]or
hand over the general management of the patien[illegible]n
life to him, for this is a responsibility which cannot properly be delegated.

It must never be forgotten that medicine is still an extremely inexact science, with certain refreshing exceptions. We do not know why one case of pulmonary tuberculosis will go steadily downhill from the start, while another, diagnosed comparatively late, will develop a life-saving fibrosis; nor can we foretell that one primipara will have a baby in two hours and another only in two weeks. Consequently, where we get to cases where genuine scientific data are few or absent, we should expect a still greater irregularity in the course they run and in our prognosis; and it is here, of course, that we fall back unconsciously upon what is termed the art of medicine. And although, like other arts, the best work is no doubt done instinctively, yet there is much to be learned from getting to know what sort of people we are dealing with in each case. This art is required to a large extent even when there are definite physical indications. Can we type our patients also in respect of their mental pattern? I think we can, so long as we have patience with people whose psychological type does not happen to correspond with our own. In the first place, the extraverted and introverted types should be recognisable to some extent in most patients with good effect. It is characteristic of an introvert to brood; thus it is not of the slightest use for an extravert doctor to leave the patient with the dictum, "Don't brood." It is better for him to suggest some occupation in keeping with the sort of subjects in which the patient is in natural sympathy—for example, people disappointed of childbearing may adopt a child with great success. The introvert, it must be remembered, must be made to extravert himself, to restore the balance. A much harder problem is to get the extravert neurotic better; it is of no use to say to him, "Don't do so much," or "Rest more." Keeping still outside the limits of normal physiological rest is as wretched to him as

Halifax Royal Infirmary.—Third H.S. £150.
Hampstead General and N.W. London Hospital, Haverstock Hill, N.W.—Cas. Surg. O. for Out-patient Dept. At rate of £100.
Hospital for Sick Children, Great Ormond-street, W.C.—H.P. and H.S. Each at rate of £100.
Hospital for Women, Soho-square, W.—Res. M.O. At rate of £100.
Ipswich, East Suffolk and Ipswich Hospital.—H.S. £120.
Kendal, Westmorland County Hospital.—H.S. At rate of £200.
Leeds, Jewish Herzl Moser Hospital, Leopold-street.—R.M.O. £200.
Leeds University.—Part-time Lecturer. £400.
Leicester Royal Infirmary.—Two House Surgeoncies. Each £125.
Liverpool. Walton Hospital, Rice Lane.—2nd Sen. Asst. Res. M.O. £350.
London Lock Hospital, 91, Dean-street, W.—Surg. Reg. £100.
London Lock Hospital, 283, Harrow-road, W.—Res. M.O. At rate of £175.
National Hospital, Queen-square, W.C.—Hon. Dental Surgeon.
Newcastle General Hospital.—Part-time Surg. Reg. £250.
Newcastle-upon-Tyne Hospital for Sick Children.—H.P. Sen. and Jun. H.S. Each at rate of £100.

to neurotics than is generally imagined. The selection of the particular form best adapted to any individual patient is one of the ways—but only one—in which the art of medicine may manifest itself. It illustrates well the conception of the art of medicine as I understand it—the art of applying to a patient the personality of the doctor, and the effect of a psychological affinity between patient and doctor upon the pattern of the life of both of them, but especially on the pattern of the life of the patient.

LIESEGANG RINGS

ABOUT thirty-six years ago Liesegang, in staining some histological material by the Golgi method, discovered that the banding phenomenon there observed was an artefact produced by the interaction of silver nitrate and potassium bichromate. He showed this by placing a drop of silver nitrate solution upon a film of gelatin containing potassium bichromate when the now familiar concentric rays of silver chromate were deposited at increasing distance from each other as their distance from the centre increased. This was the beginning of the study of the general phenomenon associated with the name of Liesegang. The subject has attracted the attention of chemists, physicists, geologists, and biologists, all of whom have sought for a common explanation of the banded phenomenon occurring in their own particular field, but, as yet, no universal explanation is forthcoming, and it may well be that otherwise similar phenomena may be brought about by a variety of causes. The ignoring of this possibility has led some authors to describe as Liesegang rings due to internal causes some forms of rhythmic banding which are clearly due to external causes—such as diurnal or seasonal changes. A large amount of literature has grown up around this subject and the bibliography at the end of a book recently published by E. S.

Hedges, D.Sc.,[1] gives 482 references. This book contains a chapter on properties of colloidal media, before discussing the Liesegang phenomenon and the theories which attempt to explain it. The two following chapters are concerned with periodic diffusion structures without chemical reaction. In this connexion it may be noted that the author objects to the description of the reactions which produce Liesegang bands as "rhythmic reactions," since there is nothing to suggest that the reactions are periodic; the periodicity is spacial, not temporal. Periodic reactions are those in which the reaction velocity varies periodically, while Liesegang bands are periodic structures. One of the most interesting chapters is that in which Dr. Hedges has assembled a motley collection of periodic structures of natural origin which are presented with the aim of helping "physical-scientists and biologists towards an A reciation of the other's point of view." The book impre first one in the English language devoted to that he ous phenomenon.

CHOLERA IN SHANGHAI

Wu Lien Teh's account [2] *of the cholera epidemic* Shanghai in 1931 is of special interest owing to ne fact that it was only in July, 1930, that the Chinese National Quarantine Service took over the control of port health work at Shanghai from the Maritime Customs Department. A precedent for this change existed in the post office, which also was originally administered by the customs authorities, but was transferred to the national postal department in 1911. It is said that great developments have occurred in the latter instance, and Dr. Wu is able to show that much progress has similarly been made in sanitation and quarantine arrangements in the short period since the new government department, of which he is the head, came into being. The transfer of control, he says, has been effected smoothly and satisfactorily, and the customs authorities and representatives of shipping interests, many of whom of course are Europeans, have rendered every support and assistance. To form a purely Chinese administration of this kind in earlier times would have been impossible, but in the last 30 years a new generation of doctors has come into existence, many of whom have studied in the best colleges of Europe, America, and Japan, as well as China. The Ministry of Health had the assistance of Dr. C. L. Park, head of the quarantine service of Australia, and chief of the epidemiological division of the health section of the League of Nations, in drawing up their new regulations. China has ratified the international sanitary convention of Paris, and every effort has been made to keep abreast of the times, and to reconcile the different and often conflicting interests of an international port.

Cholera occurs to some extent in Shanghai every year but, judged by Indian standards, few of the epidemics have been really serious. The chief significance of the outbreaks has lain in the importance of the port from the shipping point of view. The population of Shanghai in 1931 is given as 3,027,419. In the last ten years the worst epidemic, that of 1929, accounted for 3571 cases, with 313 deaths, and in 1924 only 12 cases occurred. In 1931 there were 482 cases, with 57 deaths. Noteworthy features were the diffuse nature of the outbreak, the foreign concessions showing almost as great a percentage of cases as Greater Shanghai, and the low death-rate, which only amounted to 11·8 per cent. Extensive floods occurred in the Yangtze valley in the autumn, and many refugees were assembled in camps, where things would have been much worse if early precautions had not been taken against the disease. With regard to the origin of the epidemic, Dr. Wu is of opinion that the densely populated Shanghai district must now be regarded as an endemic area, although attention should be directed to the old and crowded city of Ningpo, only one night's journey by steamer, where infection has been known to exist for centuries. On the present occasion the precaution was taken of inoculating the crews and passengers of all vessels coming from Ningpo. In the Shanghai area, the three sanitary authorities—those of the International and French concessions and Greater Shanghai—coöperated to carry out prophylactic measures. Extensive campaigns of propaganda were initiated, enlisting the help of scouts and guides, and inoculation was pressed. Apparently there is little objection on the part of the Chinese to inoculation. Cases were investigated, wells disinfected, and supplies of medicine issued free to the sick. Where the water-supply was known to be defective public artesian wells were opened. In the whole area 761,279 inoculations were performed; it is stated that of the 482 persons attacked by the disease not one had been inoculated.

OPEN-AIR AND COVERED SWIMMING POOLS

GOVERNMENT assistance to local authorities has encouraged the provision of public bathing pools during the past few years. Mr. H. R. Austin, writing in *Municipal Engineering* of Sept. 1st, mentioned the large number of authorities who have limited their schemes to the construction of open-air pools. Bathing in the open air is undoubtedly much more pleasant than bathing in an enclosed swimming bath, but our climate makes it a luxury to be enjoyed rarely, except by the hardiest; this at least appears to be the usual experience of bathing pool authorities. Mr. Austin considers that in an urban community the swimming bath should have "a definite place (*a*) as a centre for physical training of a special kind, and (*b*) as an area for exercise, recreation, and sport." To fulfil these functions he thinks that the bath should be in use during the day for the instruction of school-children in swimming, and during the evening there should be opportunity for both sexes to practise. It is impossible to carry out this full programme in an open-air bath all the year round. It is true that six hot days in the year will bring in a revenue from an open-air bath which makes a fair showing in the annual accounts, but this does not mean, necessarily, that it meets the needs of the district. Mr. Austin thinks that the solution lies in providing a comparatively small covered pool which can be used all the year round, in a central position, and a large open-air bath which could accommodate hundreds on infrequent occasions. It should not be beyond the ingenuity of those concerned to devise a swimming bath with a sliding roof, or when the pool is in pleasant surroundings, with detachable walls on the south and west sides, so that in really warm weather the swimmer can have the added amenities which make open-air bathing immeasurably more attractive than a plunge in a closed swimming bath, however well devised.

THE
BRONCHOSCOPE IN THE TREATMENT OF PULMONARY SUPPURATION

By A. J. Scott Pinchin, M.D., F.R.C.P. Lond.

PHYSICIAN TO CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS, VICTORIA PARK; TO WEST LONDON HOSPITAL; AND TO HAMPSTEAD GENERAL HOSPITAL

AND

H. V. Morlock, M.C., M.D., M.R.C.P. Lond.

ASSISTANT PHYSICIAN TO CITY OF LONDON HOSPITAL FOR DISEASES OF THE HEART AND LUNGS; TO MILLER GENERAL HOSPITAL; AND TO HAMPSTEAD GENERAL HOSPITAL

In a recent paper[1] we published an account of the diagnostic uses of the bronchoscope in pulmonary diseases, and called attention to the fact that we were using bronchoscopic drainage as a therapeutic measure in the treatment of acute and chronic pulmonary suppuration. In the present paper we propose to report on the results of this form of treatment in pulmonary suppuration.

Abscess of the Lung

Some two years ago we reported[2] on the treatment of a series of 27 acute and chronic lung abscesses. Of the acute ones, when treated by general medical measures, only 68 per cent. healed; 20 per cent. became chronic and required surgical measures; and 12 per cent. died. Of the chronic ones, but a single success was obtained by medical treatment alone. The surgical treatment yielded a 43 per cent. mortality. Since publication of that article we have had more chronic cases dealt with by surgical measures, and at present the figures stand as follows: healed, 65 per cent.; mortality, 35 per cent.

The results in the acute cases were comparatively sfactory, but the results of the chronic cases left be desired.

ch reports from abroad suggested that fit might accrue from bronchoscopic ir authors as a whole did not seem pressed with this method; Chevalier s visit to this country impressed on us, description of results attained, that it might possible to do much in this direction—even more than he claimed for the method. Despite Jackson's good results, reference to Baumgartner's[3] and also Lilienthal's[4] recent brochures shows that the surgical mind still regards bronchoscopic methods as very much of a side-line in treatment. It appeared to us that the physician in charge of the case should be in the best position to determine its suitability for bronchoscopy, and, if necessary, also to carry out the treatment; for, as we have found, to get good results it is essential that the chest should be examined carefully and frequently during the course of treatment lest any extension of the disease or other complication occur.

We therefore inaugurated at Victoria Park Hospital a bronchoscopic clinic for dealing with these cases, though we may frankly say we expected nothing dramatic in the way of results. In our efforts we have been fortunate in securing the goodwill of our colleagues, who have greatly helped by allowing us to treat some of their patients by this method.

In recording these results in a condition which, even if not becoming actually more frequent, is certainly becoming more frequently recognised, it is our intention to stress the value of bronchoscopic treatment; at the same time we do not in any way put forward the dogma that all cases should be thus treated. One can but submit results.

We recognise that it is possible that we may have been fortunate in the cases which have come to us, though many of these were of long duration, up to two years; further, in the case of abscess it is impossible to say at what period a cure has been obtained, for the cure rests in the end in the healing of a cavity, and as long as a cavity remains there is danger of the mucous membrane becoming reinfected and the disease lighting up again; on this account, if cures are counted after an arbitrary period of say six months, recurrences may occur in the seventh rendering the figures fallacious.

In the case of surgical cures the same thing happens. The abscess may recur, or sinuses, &c., may remain, which may light up and render further operation necessary, and by this and other complications lead to the death of the patient.

When therefore we speak of a cure, we indicate that a patient, who has come to us a very sick person (and there are few patients more sick than those suffering from the toxæmia and cough of a chronic lung abscess), is brought again to a condition of health, with no foul sputum or evidence of a residual toxæmia, and a radiogram which shows little evidence of infective processes going on in the lung. As our treatment of these cases has extended only over a period of 18 months, and some are still in process of cure, and as it has to be continued often in very chronic cases for six months, we can only reckon as complete cures those cases who came during the first 12 months of this time.

The consensus of opinion is that an acute case failing to heal in two to three months should be referred for surgical intervention; but we find that, *if free drainage can be obtained in any way*, the abscess will heal, and it is the possibility of obtaining free drainage by means of the bronchoscope that enables a cure to be made by this method.

METHOD OF TREATMENT

During the last 18 months we have treated 8 acute and 17 chronic cases by bronchoscopic drainage and lavage. In dealing with these cases, our mode of procedure is as follows:—

In a case suspected of abscess, an ordinary radiogram is first taken antero-posterior and lateral, and sometimes oblique as well, and if this gives any evidence of abscess a lipiodol radiogram may be taken, but if the case is to be bronchoscoped this is usually inadvisable because it spoils the result of any local injection by this means. Radiography without lipiodol may show evidence of an abscess or not; if it does it gives some idea as to the area in which it is to be sought in the bronchial tree. Four of our cases showed no evidence of abscess, though it was suspected clinically.

On passing the bronchoscope in any case in which the site is not known, the whole bronchial tree is systematically inspected, commencing with the right bronchus, since abscess is more frequent on this side. If pus is seen coming from any bronchus this branch is explored with the suction tube, and, if not, all the smaller bronchi are explored in turn. Sometimes with a chronic abscess which is not draining one succeeds in drawing off a quantity of very offensive altered blood and pus on the first occasion. If communication with a bronchus has not been naturally established, an opening may be made by this method; in fact, so far we have had no case in which we have not been able to get into communication with the abscess, the only one presenting any difficulty being a case in which the abscess was draining down the ascending branch of the right upper lobe bronchus; with the retrograde telescope we could see the pus coming down this bronchus, but no tube could be passed directly up it.

Having found pus, a smear is made on a microscopical slide and allowed to dry for examination for the presence of spirochætes—a method suggested to us by Dr. Roodhouse Gloyne—and an uncontaminated specimen of the pus sent for bacteriological investigation.

A small quantity of lipiodol is then injected down the drainage-tube directly into the abscess cavity, but the amount must correspond with the suspected size of the abscess cavity, as if too much is injected massing of lipiodol in the alveoli obscures the picture. The patient is then radiographed again (antero-posterior and lateral), and the exact position of the abscess is defined. These pictures are invaluable if surgical procedures become necessary. At the next therapeutic bronchoscopy the exact position of the abscess is already known, the bronchus of drainage can be discovered and dilated—or the œdematous granulation tissue surrounding and obstructing can be cauterised—and a drainage-tube can be inserted. Pus is aspirated via this tube by means of a suction pump, the cavity is then washed with a small quantity of antiseptic saline solution; and, finally, 10–20 c.cm. of 10 per cent. Gomenol is instilled and left there; or, if the sputum contains spirochætes, a solution of novarsenobillon is substituted for the gomenol.

Table showing Results of Treatment

R.L., R.M., and R.U.= Right lower, middle or upper lobe respectively. L.L. and L.U.= Left lower or upper lobe. Op.= operation. Imp.= improvement.

At first, in the acute cases, this bronchoscopic treatment is repeated twice weekly, and it is usually found that about five are sufficient to cause the abscess to heal. In our series the least number required was 3, the greatest 16, and the average 6. In the chronic cases the treatment is repeated at weekly intervals, but in these cases the number of treatments required is very considerably greater than in the acute cases, the least being 8, the greatest so far 28, and the average 14, although Jackson has reported a case which healed after 70 treatments.

RESULTS

On these lines we have treated eight *acute cases*, of which seven are healed and the eighth is well on the way to cure. This is a very small series, but it would suggest that bronchoscopic drainage in acute cases produces better results than general medical treatment alone.

Of 14 *chronic cases* ten are healed, three are likely to heal in view of past experience, and one was referred to the surgeon. It will thus be seen that in chronic lung abscess bronchoscopic drainage offers more chance of success, with smaller mortality, than surgical measures.

The Table includes all cases of abscess which we have systematically treated. There have been no deaths in our series, though there is doubtless an element of good fortune in this, since any case of lung abscess may develop a cerebral abscess or other troublesome complication.

NOTES ON SOME CASES

CASE 9.—Had an abscess draining from the internal division of the terminal lower lobe bronchus on the right, the abscess was in the angle of the diaphragm and the mediastinum; surgical exploration had failed to locate the abscess, phrenic avulsion and artificial pneumothorax had also been tried without result.

CASE 10.—A right apical abscess which was progressing well and, judging by other cases, would probably have healed by bronchoscopy. He was one of our early cases at a time when we were still doubtful as to results. He desired an operation, and being an eminently suitable case for surgery we asked Mr. R. H. O. B. Robinson to operate; he made a good recovery.

CASE 14.—Is now practically dry, but cannot yet be classed as cured.

CASES 18 and 20.—Were transferred from a general hospital after phrenic avulsion, which had made them worse. Case 20 had several abscesses, and seemed a quite unlikely case to improve; there is, however, every prospect of a cure, and he is back at his work, which is of a hard manual character.

CASES 23, 24, 25.—As in simple bronchiectasis cure can scarcely be expected in this type of case, but it is possible to ameliorate the condition.

In Case 23 surgical operation has been refused, and Cases 24 and 25 are unsuitable for surgery.

Four other cases of lung abscess have come under our observation during the last 18 months in which bronchoscopic treatment was not indicated.

A woman with 18 months' history who had absolutely refused all treatment for six months. She was finally admitted with a secondary empyema which was drained by Mr. Robinson; she was making a good recovery, but the day she was going out of hospital died suddenly of pulmonary embolism.

A man with secondary empyema treated by extensive resection of rib and drainage. Recovered.

A man with cerebral symptoms who died of a secondary cerebral abscess.

A child of 7. Influenzal pneumonitis, followed by a large hæmorrhage and abscess formation. Recovered on medical treatment.

Bronchiectasis

The number of abscesses we have had for treatment in the last 18 months, with other cases for diagnosis and treatment, has necessitated 650 bronchoscopies, and time has not permitted of us taking on more than a limited number of bronchiectases. We have seen 30 of these during the period, and have regarded most of them as quite unsuitable for curative treatment, though all of them are undoubtedly better for regular lavage and drainage. The idea that one or two bronchoscopies can cure a bronchiectasis is, of course, quite absurd, considering the pathology of the disease, but there is no doubt that with regular drainage, lavage, and antiseptic medications, the condition of the patient can up to a point be very much improved by this means. We have been able to improve the condition of those patients treated regularly so that they have been able to resume their employment.

METHOD OF TREATMENT

At the commencement of treatment an ordinary lipiodol examination with 40 c.cm. of lipiodol is given to ascertain the extent of the bronchiectasis. In those cases in which a small area only is suspected this can best be done via the bronchoscope by means of which localised areas can be delineated without flooding the rest of the lung. In some cases, when obstruction has taken place from œdema of the mucous membrane high up the bronchial tree, the greater part of the lung may be full of pus, and this can be cleared at the first drainage and lipiodol injected.

On examination of the case bronchoscopically it is noted from which bronchi the pus is coming, this part is as far as possible sucked dry, and the drainage-tube or dilator passed down the various subdivisions of the bronchi to give free exit to the pus. If the cavities are large, saline antiseptic solutions may be used for washing out. We then usually inject gomenol, or when spirochætes are present a solution of N.A.B., which is also used intravenously.

This course is carried out each week for about two months, after which the treatment may be gradually reduced. Some of our patients now come only every six weeks for treatment.

It cannot be suggested there is much possibility of final cure; for these fibrosed sacs to close would take a very long while, and is almost too much to expect.

The use of lipiodol may be of considerable service in the following way. When lipiodol is injected into the bronchial tree, on account of its density it finds the lowest level, displacing the secretion from the most dependant parts in which it has become completely stagnant; but this is purely mechanical, and lipiodol has little antiseptic effect. Antiseptic solutions injected only lie on top of the secretions. In an endeavour to obtain the gravity effect of lipiodol, with an antiseptic effect, we have used lipiodol with 10 per cent. gomenol added, and by this means the antiseptic is carried to the lowest part of the diseased area, and has a very salutary effect. Whatever the means employed, the result is that the mucous membrane of the bronchi above the lesion recovers in health, and the cough reflex is re-established. Though, as before stated, we cannot prove that frequent lavage will go far in curing a chronic bronchiectasis, until cases have been watched for some years, yet we are able to produce a condition of health so that the patient can carry on his occupation and cease to be an offence to his neighbours.

OTHER REMEDIAL MEASURES

Against this result we must consider the other methods of treatment. Postural drainage and the creosote chamber fail inasmuch as the drainage cannot be complete because of the turgescence of the mucous membrane above the lesion—the cause of the trouble. The most reasonable method of treatment is lobectomy, but the lesion must be confined to one lobe; moreover, it should be done early, at a time when the patient is still quite well. At this time one hesitates to recommend an operation which has a mortality-rate of upwards of 30 per cent., when there may be expectation of life without the operation of ten years or more. From phrenic avulsion we have seen little good result; previously we have tried it in a number of cases, but have failed to see any permanent benefit. In evaluating the results of phrenectomy it must always be remembered that bronchiectasis will improve spontaneously from time to time, and the reports of good results following this operation are found in cases which have only been watched for a short period after operation. Not only do we regard the operation as valueless, but, in the light of recent experience, as distinctly harmful, for, if one views these patients with the bronchoscope, one will see that the force of their cough is greatly reduced, and when one remembers that the one method the patient has of emptying the bronchus is by coughing, the fallacy of this operation is apparent.

Thoracoplasty may reduce the volume of cavities, but is seldom successful in completely closing them, there being no active repair changes going on as in a tuberculous cavity; the patient may be improved, but is still bronchiectatic, and liable to fatal complications. Artificial pneumothorax collapse obtained by this method is seldom, even in slight cases, sufficient to bring the walls of cavities in apposition, and we have not obtained complete cures by this method, even when we have replaced the air by gomenol.

Summary

In our small series of acute cases bronchoscopic drainage in addition to medical treatment seems to produce a definitely higher proportion of cures, compared with medical treatment alone.

In chronic abscess when medical treatment was of no avail bronchoscopic drainage has succeeded in producing a cure in nearly every case, without loss of life, whilst surgical procedures which we have had done in the past have produced 65 per cent. cures with 35 per cent. loss of life; in addition some of the cures have been left with persistent sinuses very hard to heal and often necessitating several plastic operations.

In bronchiectasis, abscess with bronchiectasis and bronchiectatic abscess, although producing no radical cures, bronchoscopic drainage is a palliative measure of very considerable value.

VARIATIONS IN THE IODINE CONTENT OF THE BLOOD

IN HYPERTHYROIDISM AND NON-TOXIC GOITRE

BY E. C. DODDS, M.V.O., M.D. LOND.
COURTAULD PROFESSOR OF BIOCHEMISTRY, UNIVERSITY OF LONDON

W. LAWSON, M.SC., A.I.C.
SENIOR ASSISTANT

AND

J. D. ROBERTSON, M.D., D.P.H.
ASSISTANT CHEMICAL PATHOLOGIST, MIDDLESEX HOSPITAL

(From the Courtauld Institute of Biochemistry, Middlesex Hospital, London)

SINCE the original announcement by Gley and Bourcet[1] in 1900 of their discovery that iodine is a constant and normal constituent of blood, attempts have been made repeatedly to establish a connexion between diseases of the thyroid gland and variations in the blood iodine content. This problem has been surrounded with the greatest difficulties owing to complications in the analytical methods. The amount of iodine present in the blood under normal conditions is very small indeed, and hence investigators were hampered both by having to use complicated micro-methods and by being compelled to use relatively large quantities of blood.

In the first place, the normal variations in the iodine content of the blood have been expressed by various workers to lie between some 5–20 γ per 100 c.cm.* Kendall and Richardson,[2] in 1920, stated that the variations found by them ranged from 10 to 17 γ with an average of 13 γ per 100 c.cm., whilst in 1925 Veil and Sturm[3] pointed out that there was a seasonal variation with an average figure of 12·8 γ in the late summer and 8·3 γ in the winter. In 1926 a very important paper by von Fellenberg established firstly the method and secondly the normal figures.[4] Maurer and Diez[5] in 1926 found an average of 9·2 γ, with upper and lower limits of 15 γ and 4·2 γ respectively. Jansen and Robert[6] in 1927 reported an average of 12 γ per 100 c.cm., with a maximum of 16·2 γ and a minimum of 10 γ. It would appear therefore that the majority of workers agree to an average figure for total blood iodine in the normal person of about 8–13 γ per 100 c.cm.

Turning to the pathological side, it has been maintained by various workers for some considerable period that there is a relationship between the activity of the thyroid and blood iodine content. Thus, following thyroidectomy, Sturm and Buchholz[7] state that the blood iodine content of the dog falls. The amount of carefully controlled work, however, on this point was very small until the publications of Holst,[8] Lunde,[9] and their co-workers appeared. These workers wished to study the relationship between the iodine content of the blood, the basal metabolic rate, and the degree of toxicity of patients with hyperthyroidism. In the first place, they came to the conclusion that mere estimations of the total iodine content of the blood were of little value since this was greatly influenced by iodine and iodides which had been taken by mouth. They therefore devised a method of fractionating the iodine content of the blood into two parts, one soluble in alcohol and the other insoluble in alcohol. The alcohol insoluble fraction represents, according to their statements, the iodine-containing substance circulating in the blood, which is presumably responsible for the toxic symptoms. This, they assumed, was also secreted by the thyroid gland. In the normal person they found that the alcohol-insoluble fraction was constant at some 1–4 γ per 100 c.cm., and the alcohol-soluble fraction varied from 7–12 γ per 100 c.cm. If inorganic iodides or iodine were administered by mouth then there was an immediate rise in the alcohol-soluble fraction, whilst the alcohol-insoluble fraction remained unaffected.

A series of cases of hyperthyroidism was very carefully studied by these workers, and it was shown that at the outset, before any iodine treatment was given, the alcohol-insoluble iodine content of the blood was very much above normal, its amount corresponding roughly to the extent to which the basal metabolic rate was raised. If the patient was then treated with iodine by mouth, the basal metabolic rate fell, as was shown by Plummer,[10] and they demonstrated in the cases studied by them that the alcohol-insoluble iodine also fell, pari passu, with the basal metabolic rate. When the basal metabolic rate had fallen to normal, the alcohol-insoluble iodine *content was also within normal limits, and thyroid*ectomy was performed at this point. The basal metabolic rate thereafter remained at a low or normal level, and the alcohol-insoluble iodine content of the blood also remained within normal limits. It appeared from their results that there was a definite correlation between the basal metabolic rate and the alcohol-insoluble iodine, and, since the gradual disappearance of signs of intoxication and the reduction of the basal metabolic rate went hand in hand with the fall in this fraction of the blood iodine, they put forward as a definite conclusion that determination of this substance in the blood would give as reliable evidence of the toxicity of the case as the basal metabolic rate would, and that in effect this fraction represented the basal metabolic rate-raising substance secreted by the thyroid in such conditions. The importance of this suggestion is obvious to all interested in the problem of toxic goitre, and so naturally formed the starting point of this investigation. It was decided in the first place to repeat the work of Holst, Lunde, and their co-workers, with a view to extending it later by attempting to elucidate the chemical nature of this organic iodine compound which was insoluble in alcohol. The investigation described consists of (*a*) an inquiry into the methods used for the determination of iodine in the procedure adopted by Lunde, and (*b*) the application of this method to the study of cases undergoing treatment.

Determination of Iodine

The method used for the estimation of iodine in this investigation is that of von Fellenberg,[4] as modified by Lunde.[9] [11] Briefly, the method is as follows :—

10 c.cm. citrated blood are added to about 40 c.cm. iodine-free alcohol and thoroughly shaken. The finely divided coagulum is extracted in a Soxhlet's apparatus for four hours. This period of extraction is sufficient to remove all the alcohol-soluble iodine-containing substances, since experiments have proved that further extraction up to 100 hours gives no appreciable increase in the quantity of iodine extracted.

For the ignition to destroy organic matter the two portions are transferred to flat, stainless iron dishes. To the insoluble fraction is added 8–10 c.cm. 50 per cent. potassium hydroxide solution, and to the alcohol extract 1·5 c.cm. saturated aqueous potassium carbonate. The contents of the dishes are evaporated to dryness on a waterbath, and then heated gently at first, and finally to 400° C., till the odour of burning organic matter has almost disappeared. The mass is then dissolved in the smallest possible quantity of water, and hard lumps are crushed with a pestle. The solution is again evaporated and heated, and the whole operation is repeated until a white ash is obtained which gives a clear and only slightly coloured solution. After the final evaporation and ignition. water is added drop by drop, whilst grinding with an agate pestle until a thick paste is obtained, which is extracted first with 10 c.cm., and then with three portions of 3 c.cm. 95 per cent. alcohol. The extract is evaporated to dryness in a small gold-platinum dish with about 5 drops of saturated potassium carbonate solution. and the dish is cautiously heated over a free flame. care being taken that the bottom of the dish does not attain red heat. This ash is then extracted with three portions of 3 c.cm. alcohol in a similar manner to the first extraction.

---

* 1·0 γ = 0·001 mg.

The final extract is evaporated to dryness, and the residue is dissolved in about 3 c.cm. water and carefully transferred to a small Erlenmeyer flask (25 c.cm.). One drop of 2 N sulphuric acid and about 0·25 c.cm. freshly prepared bromine water are added. and excess bromine is removed by boiling for one minute. After the addition of a minute crystal of potassium iodide the liberated iodine is titrated with a N/1000 solution of sodium thiosulphate. Experiments performed with pure potassium iodide added to pure potassium carbonate solution have shown that the extraction of iodide by alcohol is completely quantitative, provided that only sufficient water is present to form a paste. These experiments confirm the findings of Aitken.[11]

In check experiments on the complete estimation we have succeeded in recovering 85–90 per cent. of iodine added to the alcohol-insoluble fraction from 10 c.cm. blood in the form of organic iodide or thyroxin in amounts corresponding to 1 γ of iodine.

Reagents were purified by the methods described by Lunde and von Fellenberg,[12] and all estimations were carried out in duplicate.

Clinical Application

Having ascertained the limits of accuracy of the method and established in a satisfactory manner the normal values for men and women of the age of the goitre patients. a number of patients with toxic goitre undergoing treatment in the hospital were selected for observation. These patients were all treated as in-patients and the procedure was as follows: they were admitted to the surgical wards of the Middlesex Hospital. and the basal metabolic rate was determined at intervals throughout the course of the investigation by means of the Benedict-Roth apparatus. The standards of Aub and Dubois were employed. Prolonged experience in this laboratory with this method has shown that the experimental error is no more than 5 per cent. The patients were rested in bed without any treatment until the basal metabolic rate was constant. and specimens of blood were then collected and the iodine determinations performed. Iodine was then administered daily in a dose of 180 mg. per day in the form of Lugol's solution. and specimens of blood were collected during the course of the treatment. When the basal metabolic rate had fallen to normal, or had remained at a constant low level for two days, subtotal thyroidectomy was performed, the iodine was stopped. and whenever possible specimens of blood were collected after the operation. The patients after their discharge from hospital were seen at various periods for determinations of their basal metabolic rate. and the blood iodine distribution was also studied. The results are set forth in a series of tables.

TABLE I.—*Normal Persons*

Average: 3·95 γ per 100 c.cm.

In Table I. will be seen the findings in 16 normal people. with five over the age of 40. The average value for the alcohol-insoluble portion of the blood iodine is 3·95 γ per 100 c.cm.. and may be taken as the normal figure for the age of the various patients in our series. The highest reading obtained was 5·7. and the lowest 2·4. These figures do not differ markedly from those already published by previous investigators.

* Operation on 16th day when B.M.R. had come down.

Table II. shows the results of simultaneous determinations of basal metabolic rate and alcohol-insoluble iodine content of the blood in relation to treatment of patients with iodine. After a preliminary period of rest, the basal metabolic rate was determined and the blood analysed. Immediately following this, 180 mg. of iodine per day were administered in the form of Lugol's solution, and the basal metabolic rate was determined at intervals. When it had reached its lowest point the patient was bled, and the results are reported in the Table. A very careful scrutiny of the various figures reveals in the first place that in almost every case the alcohol-insoluble fraction of the blood iodine is raised. and that after treatment with iodine it is reduced in quantity. This bears out the findings of Holst, Lunde. and their co-workers, in so far as they state that this fraction is always increased in toxic goitre and falls after the administration of iodine. It can be seen that there is no relationship between the fall in alcohol-insoluble iodine content of the blood and the basal metabolic rate. Reference to details in the Table demonstrate very clearly that the two do not go hand in hand. It would appear, therefore, that this series of observations constitutes a very serious blow to the theory put forward by Holst and his colleagues that the alcohol-insoluble fraction of the blood iodine is definitely a measure of the toxicity of a case of exophthalmic goitre. It was decided to conduct a series of experiments to elucidate, if possible, the significance of this fraction of the blood iodine content.

It would be familiar to all who are experienced in the treatment of these cases that immediately after operation there is a rise in temperature and basal metabolic rate and, in fact, an exacerbation of the symptoms of the case. This has usually been attributed to a squeezing out of the toxic secretion which produces the symptoms during the process of removal of the gland. A series of patients was therefore taken and blood was collected immediately before operation and again immediately after operation. The alcohol-insoluble fraction of the two specimens was estimated and the results will be seen in Table III. The results indicate that the exacerbation of the symptoms following operation cannot be attributed to an increase in the alcohol-insoluble fraction of the blood iodine.

In order to ascertain whether there was any fixed relationship between the basal metabolic rate and the alcohol-insoluble fraction of the blood iodine at any given moment, a series of simultaneous determinations of these two figures was made, and these are set out in Table IV. Again it is only possible to generalise, and to state that in the main a high basal metabolic rate is associated with a high alcohol-insoluble blood iodine content, but there is no quantitative relationship between the two; nor, as a matter of fact, does the reverse hold true, and the Table demonstrates that it is possible to have a low iodine fraction associated with a very high basal metabolic rate. It must be admitted that this series of results again casts grave doubt upon the validity of Holst's hypot In order to provide control observations, a seri patients with non-toxic goitre were examine simultaneous determinations of basal metabolic and blood iodine. These patients, of course, wer treated with iodine. It can be seen that in a nu of them, although the basal metabolic rate was no or subnormal, the alcohol-insoluble blood i content was considerably raised.

General Conclusions

The results set forth in this paper indicate, fir that Lunde's claim for the separation of the b iodine into two fractions by means of alcohol ext tion is justified and that these two fractions vary different manner. They also confirm the fact that insoluble fraction is increased in quantity in patients with toxic goitre, and *that this amount* be reduced by oral treatment with iodine. The ca simultaneous determination of basal metabolic has shown, however, that this fall is not necessa *associated with a reduction in the toxicity and* basal metabolic rate. The number of cases exami by Holst and Lunde and their co-workers is very much smaller than the series studied by us, and it is along this line that the discrepancy is to be explained. It would be quite possible to find a series of patients in which the reduction in the basal metabolic rate corresponded to the reduction in the alcohol-insoluble blood iodine content. It is to be noticed that in the series published by Holst in his monograph, all the patients responded well to the iodine treatment. In refractory cases the alcohol-insoluble blood iodine content falls, yet the basal metabolic rate and toxicity will still remain high. The conclusion, therefore, is forced upon us that the alcohol-insoluble fraction does not represent a measure of the toxic secretion by the thyroid. The observations on cases of simple and non-toxic goitre amply confirm this view, and it must be admitted that the solution to the nature of the pathological secretion of the thyroid gland very definitely does not lie along the line of study of the total alcohol-insoluble fraction of the blood iodine content.

We have to thank Mr. R. Vaughan Hudson for supplying us with the clinical material described in this paper. It is a pleasure to record our thanks for his coöperation in the research.

One of us, W. L., wishes to thank Dr. Lunde for his courtesy in demonstrating the method for the estimation of the iodine in his laboratory in Stavanger.

STENOSIS OF THE COLON IN INFANCY

BY ANNE E. SOMERFORD, M.D. MANCH.,
D.P.H. CAMB.

PATHOLOGIST TO THE ROYAL MANCHESTER CHILDREN'S HOSPITAL, THE MANCHESTER NORTHERN HOSPITAL, AND ST. MARY'S HOSPITALS, MANCHESTER

FOUR CASES

CASE 1.—A. B. was a full-term child, apparently normal at birth, but it was noticed that a motion was only passed every third day, and there were occasional attacks of vomiting. As he was obviously failing he was admitted to hospital when a month old. In hospital the vomiting gradually ceased, and with the aid of daily rectal lavage two or three motions were passed daily, but in spite of treatment death took place 14 days after admission.

Permission for a *post-mortem examination* of the abdomen only was obtained, and the following conditions were found:—

There was no free fluid in the peritoneum, but the intestines were bound down with adhesions. The small intestine, stomach, appendix, and cæcum were normal, except for adhesions. The ascending colon was somewhat dilated, but its coat was not hypertrophied. It contained a fair quantity of soft, yellow fæces. The hepatic flexure did not present any stenosis. The transverse colon was very much dilated, and was filled with a huge quantity of yellow fæces. At the splenic flexure there was a very definite narrowing of the gut, and here the muscle tissue was increased, apparently forming an obstruction to the flow of bowel contents. The descending colon and sigmoid were also distended, but to a much lesser degree, and there were no contents. There was no thickening at the junction of the sigmoid colon and the rectum. The dilatation which was present below the obstruction was probably due to atony, and comparable to the ballooning sometimes seen below a malignant growth.

Microscopical sections were made of the bowel wall above, below, and at the point of stricture, and an increase of muscle tissue was found in the constricted portion as compared with the other two sections. Also there was a subacute but active inflammatory process in the submucosa, most marked in the stenosed section, but present also in the others.

CASE 2.—Until he was 8 months old C. D. was perfectly well and gained weight rapidly. Then the bowels became somewhat constipated, but otherwise he seemed healthy, and it was decided to begin weaning. One artificial feed was accordingly given at 2 P.M. each day, and this was vomited, but the remaining (breast) feeds were taken well and retained. After seven days an attempt was made to stop all breast feeds, but the child refused them and would only take boiled water. The stools became loose, green, and copious, and he was admitted to hospital in a collapsed condition. After admission he became constipated, and an enema given on the first day contained a few flakes of fæcal material. Enemata given on the following days were without result, and no motion was passed. Vomiting ceased, but acetone and diacetic acid were present in large amounts in the urine. On the third day after admission he died at the age of 9 months.

The *post-mortem examination* showed a fat baby with distended abdomen. Apart from the abdominal findings no abnormalities were detected.

The stomach was normal. The small intestine was filled with deep green, very offensive fæcal matter. The large intestine was filled with air and was much distended. A narrowed portion, about 2 inches in length, was found in the descending colon, but air and fluid could be squeezed through it. (Fig. 1.) There were no peritoneal bands or adhesions. A section taken from the point of stenosis showed, in addition to an increase in the circular muscle coat, a great increase in fully formed fibrous tissue in the submucosa as compared with a section from the apparently healthy colon above the stenosis.

CASE 3.—E. F. was also a full-term child, and labour had been normal. For three weeks he was breast-fed, and then the supply of milk failed and Allenbury's food, milk and water mixtures, and Sunshine Glaxo were substituted, one after another. He was always delicate, and feeding was difficult, but for six weeks before admission to hospital vomiting had been frequent and on one occasion he had vomited blood. He had had diarrhœa for weeks, but for two days before admission he had been constipated and the abdomen had been distended. On admission he was a very ill, dehydrated baby. Coils of gut were visible, but peristalsis was not seen. A mass was felt in the right iliac fossa and above the pubes. Although a diagnosis of intestinal obstruction was made, operation was never considered feasible, and he died eight days later, at the age of 8 months.

The *post-mortem examination* showed a thin child with markedly distended abdomen. The large intestine showed ballooning above and below a stenosed portion situated at the junction of the descending and the sigmoid colon. (Fig. 2.) There were fibrous adhesions binding the first part of the ascending and last part of the descending colon to the parietes. There was no naked-eye evidence of ulceration or inflammation along the intestinal tract. Sections cut from the apparently normal bowel and from the wall at the stenosed part showed considerable increase in the circular muscle tissue in the latter section. There was some subperitoneal fibrosis in both sections.

CASE 4.—G. H., also a male, was a full-time baby weighing 8 lb. at birth. For 11 weeks he was breast-fed, but this diet was then changed to half-cream Cow and Gate food. There was a history of constipation since birth, and great effort was needed on defæcation. The abdomen was often distended, but there was no vomiting. On admission to hospital the abdomen was much distended and was hard on palpation, but there was no rigidity. Simple and olive oil enemata on the day of admission gave very little result. Further olive oil enemata given on the first and second days after admission produced better results, although the abdomen still remained distended. On the third day coils of gut could be seen through the abdominal wall, but peristalsis was not noticed. The child began to vomit, and vomiting continued until his death two days later, at the age of 14 weeks.

The *post-mortem examination* showed an emaciated infant with a very much distended abdomen. Apart from the lesions in the abdomen no abnormalities were found. The stomach and duodenum were normal. There was increasing dilatation of the ileum and jejunum until the ileocæcal valve was reached, and here there was an abrupt narrowing. (Fig. 3.) The first inch of the appendix was distended, and there was considerable distension of the cæcum and the ascending, transverse, and descending colon. This distension was most marked in the cæcal region and became progressively less. Large masses of hard fæces were found in the descending colon and rectum. At the junction of the descending and the sigmoid colon there was well-marked stenosis which, however, was not complete, as material could be forced through it.

Sections were cut from the stenosed portion and from the least distended portion of the bowel above. The section of the former showed considerable increase in submucous fibrous tissue and a certain amount of increase in the circular muscle tissue. The section taken of the bowel above the stenosis did not show any abnormality apart from the fact that the mucosa had disappeared, probably owing to post-mortem change.

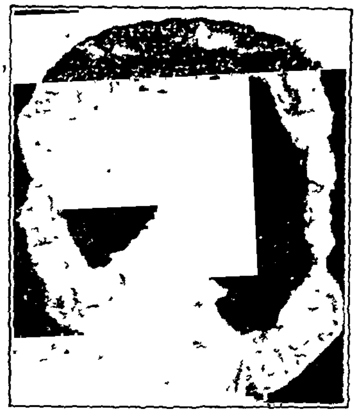
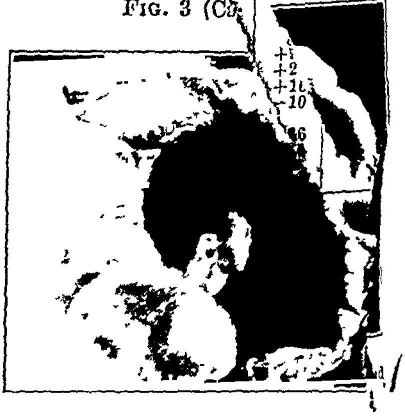
of the descending colon with ballooning below.

FIG. 2 (Case 3)



Stenosis of the colon at the junction of descending and sigmoid colon.

FIG. 3 (Case 4)



Stenosis at the junction of descending and sigmoid colon and extreme dilatation of the bowel above.

ÆTIOLOGICAL FACTORS

The origin of congenital stenosis has not yet been fully explained, but the following factors are suggested:—

(a) Embryonic disturbances of develo
diverticulum may cause fixation o
resulting stenosis. In other cases
anomalies with insufficient nour
intestine, or an ab ch
obstruct the gut.
ment atresias occ

due to cell proliferation in the already fully developed intestine; the gut at various points in consequence becomes solid. If for some unknown reason the embryonic state persists, an atresia occurs. If the embryonic state only persists in part a stenosis is the result.

(b) Mechanical causes.—An enlarged liver, a hypertrophied head of the pancreas, and congenital abdominal tumours or cysts may compress the bowel externally and give rise to symptoms of stenosis. Volvulus or intussusception in utero may cause obstruction, but the rôle of these factors in causing stenosis has been much disputed.

(c) Fœtal inflammations.—It seems quite possible that [illegible] peritonitis may cause stenosis in the intestinal wall, but [illegible] usually evidence of any such fœtal peritonitis is lacking, and when it is present it is probably rather a result [illegible] a cause of the atresia. Fœtal enteritis, which has been [illegible] postulated from the finding of overfilled vessels, swelling of the intestinal lymph follicles, and positive bacteriological results, should be regarded as a secondary process.

(d) Sex.—Since all the above cases occurred in male children, statistics have been collected as to the occurrence of other stenoses in the alimentary tract. Only Sheldon[1] reports two cases of colonic stenosis, and he unfortunately does not record the sex. Congenital stenosis of the pylorus occurs four times as frequently in males as in females, according to Feer. Still[2] had 35 males amongst 42 cases of pyloric stenosis. In my own post-mortem records there were ten males and two females. Smellie[4] reported three cases of duodenal stenosis, all of them males, and I have collected three similar cases, two of whom were male; the sex of the other was not recorded. Records of the sex-incidence in cases of stenosis of the jejunum, ileum, and rectum were not found.

TYPES OF STENOSIS

Atresias may be of varying degrees of severity
complete absence of the greater part
of the cæcum.

mery[1] described a case of congenital
cæcum and ascending colon. The patient
42 years of age, who consulted him for
sigmoidoscopy revealed the presence
colon, and the abdomen
ostomy might be made
was found: the lower part

f the ileum was dilated, and passed at once into the ansverse colon; there was a rudimentary appendix in he angle where the ileum joined the colon.

Elliot Smith[6] described a similar condition in a woman f 25 years of age. In this case the ileum passed directly nto the ascending colon, and there was no trace of any æcum or ileocæcal valve. There was a rudimentary ppendix, and the colon had a very long mesentery.

Gellert[7] reported the case of a boy aged 5 days. There vas absolute constipation from birth but no vomiting, nd feeds were taken well. He died on the sixth day of fe, and a post-mortem examination showed that the whole f the large intestine was represented by a pale contracted ibrous band, the lumen of which would only admit a noderate-sized probe. A plug of mucus completely occluded he lumen at the splenic flexure.

Walker[8] reported a congenital defect of the lower bowel ccurring in three successive children of one family. In he first two infants operation and post-mortem examination howed that the large intestine was completely absent. n the third case the child seemed normal at birth, but ithin 24 hours there was abdominal distension, pain, and emperature. Examination per rectum revealed a blind nd less than 5 cm. from the anus. Post-mortem examination was not permitted.

Schukowsky[9] collected but one case of colonic stenosis mongst 20,000 new-born children. In this child the lower uarter of the ileum, the whole colon, and the rectum were presented by a band containing hardly any lumen.

Fyfe[10] records a case in a boy of 2 days old in which e large intestine terminated in a balloon-shaped cul de sac the splenic flexure with little trace of the bowel between cept at the anus. The symptoms were absolute conipation and vomiting from birth. The child died when 3 days old.

Sheldon[1] states that only two cases of partial colonic enosis were found in 6000 post-mortem records, and is appears to be the only record of the less complete bnormalities which are described in this paper.

Although there was some increase in circular muscle tissue at each of the stenosed points in my cases, yet in two only was this a very marked feature. In one of the other two cases there were definite subacute inflammatory changes in the submucous coat; in the other there was evidence of an old nflammatory condition in the large deposition of fibrous tissue, also in the submucosa. There are thus two distinct types, one of purely muscular, one of inflammatory origin.

DIFFERENTIAL DIAGNOSIS

(*a*) *From Hirschsprung's disease.*—The symptoms in this disease and in colonic stenosis are almost identical, though pain does not seem to be a marked feature in the latter disease. On post-mortem examination there are several points of dissimilarity: in Hirschsprung's disease there is no apparent bstruction, and the muscle coat of the dilated portion (longitudinal and circular fibres) is much hypertrophied.

(*b*) *From congenital pyloric stenosis.*—In this disease vomiting is a particularly prominent symptom. It s forcible, sudden, and often copious, and its onset s usually in the second to the fourth week of life. Visible peristalsis can almost always be detected if sufficient examinations are made after a feed. Constipation and wasting are present as in colonic stenosis.

In conclusion, I should like to tender my thanks to Dr. C. Chisholm, Mr. D. M. Sutherland, and Dr. J. F. Ward for their kindness in allowing me the use of their clinical notes.

THE MENTAL EFFECT OF THE COMPLETE MASTOID OPERATION IN CHILDREN

By Macleod Yearsley, F.R.C.S. Eng.

CONSULTING AURAL SURGEON TO THE LONDON COUNTY COUNCIL AND TO THE ST. JAMES'S HOSPITAL, BALHAM

At a meeting of the Otological Society of Great Britain in 1907, Mr. Waggett spoke of the effect of the complete mastoid operation on mentality in the adult. His remarks are to be found in the Society's *Transactions* (1907, viii., 36) and the passage is worth quotation:—

> "Mr. E. B. Waggett said he had gained an impression that people who had had complete mastoid operations became extremely miserable—he scarcely liked to say neurasthenic. He had now three young women under his care upon whom complete mastoid operations had been performed, and, although as aural cases they were very satisfactory, they were constantly worrying about their general condition. The most miserable man he had ever seen lived nine years after removal of part of his cochlea and a cerebellar abscess. It was well known that the removal of organs had a depressing effect on the mind and on the whole economy, and it would be useful if evidence were collected on the subject whether the complete mastoid operation, with removal of the musculature, the ossicles, &c., had a more profound effect on the general condition than a minor operation."

The opinion generally expressed at this debate was that such result depended on the family history of the patient, and one speaker suggested that the operation might sometimes even be a means of preventing insanity. It was considered by the otologists present that cases of profound depression following the radical operation were too few to warrant an endorsement of Mr. Waggett's statement, a conclusion with which I fully agree. No mention was made of the concussive effects of the operation, nor was the pain of the dressings, often long continued, alluded to. The question of operation in children was not introduced.

Looking through the notes of a considerable number of adults cases of my own, both private and in hospital, I find that the usual result of the operation was improvement in mental as well as physical condition. It may be that some of the cases cited at the debate in 1907 were affected by the concussion resulting from the use of the mallet and chisel for an hour or more, as I find that some of my earlier cases suffered from that method of operation, a method which has, during the past 25 years, been almost entirely superseded by the cutting gouge.

AN INQUIRY

There is, however, a very considerable mental disturbance in many children following the complete radical operation, especially in those who have been operated upon more than once. My attention was drawn to this fact some time ago by teachers in the L.C.C. deaf-schools, these teachers speaking to me individually and independently. I was told that the "mastoid" children were "mentally inferior," dull, slow in the uptake, irritable of temper—all rather vague statements, but enough to suggest that a mental effect of a serious kind was present that might be worth investigation. I therefore addressed a circular letter to nine head teachers of deaf-schools asking for information on the subject, and to these ladies and gentlemen I am indebted for some interesting replies from which certain deductions may be made.

It must be remembered that the children in our deaf-schools whose defect follows middle-ear suppuration due either to an infectious fever, of which scarlet fever, measles, and diphtheria are the most serious, or to primary ear disease are usually specimens of the worst ravages of this condition. They are mostly children from poor environment, of bad stock and inferior nutrition, children who have run through the gamut of neglect and of treatment, and in whom the consequent impairment of hearing is considerable. With children whose otorrhœa has been early taken in hand and treated efficiently—and in such cases the radical operation is not needed, simple draining of the mastoid antrum usually being the most that is necessary—I have nothing to do; the great majority of them return to the hearing-schools and do not come into my ken. In this paper, therefore, I speak of the worst cases only; what ratio they bear to the others I cannot say.

The opinions expressed in the nine letters referred to may be summarised as follows:—

1. Of four boys and three girls now in the school, the response is average, but the general intelligence and memory are variable and industry and mental balance are well below that of the other children.

2. Mentality of these children is poor and takes from four to five years to recover. Very quickly exhausted at anything requiring exertion.

3. They suffer from shock for some time after. One boy, for 18 months after double radical operations, took no interest in anything and did practically no work; at the end of that time he suddenly picked up, became bright and cheerful, and commenced to work well. Other cases that returned to school straight from hospital showed similar reaction. Those operated upon some time before entering this (a secondary) school had already recovered.

4. Of 18 cases, all of good intelligence and all operated upon at an early age, the mental processes were slow in ten, three were nervous, one showed mental irritability, six lacked concentration, and one had a very poor memory. One boy remembered a period of shock after operation when thinking was difficult.

5. All mastoid children took a considerable time to recover, one boy not recovering completely after three years. All showed "nervous debility."

6. The chief characteristics of the mastoid children are: increased irritability; weak memory; want of balance in behaviour; lack of concentration. They are "worried by anything out of ordinary routine and any pressure or correction usually results in an emotional outbreak. The [illegible] moral sense appears to be affected [illegible] which does not develop, but retains [illegible] time of reaction appears to be affec[illegible] very few mastoid cases are normal a[illegible]

7. The children are dull and heavy for some time after operation.

8. "Speaking generally," all show evidence of shock to the nervous system. Whereas some overcome this in a [illegible] others carry traces of it throughout

reference to the loss of function, I would point out that in the amount of residual hearing which the operating otologist considers to be ample for education in a hearing school he is often far from being in accord with the school medical officer. This is not infrequently shown in certificates produced intimating that the child is not sufficiently deaf for transference to a special school. Not only may the operating surgeon be deceived by the child's possible power of lip-reading, but he appears to have little conception of the disturbing effect of the ever-present noise inseparable from a class of 30 or 40 children upon a partially deaf child.

The mental effect, apart from the toxæmia, of prolonged otorrhœa is probably due to long-continued pain and fear of painful dressings. The condition is one of nerve exhaustion from prolonged suffering and mental strain, leading to irritability, emotional outbursts, lack of concentration, bad memory, and want of balance in behaviour. The effect is always more marked in children who have been compelled to undergo more than one operation.

The obvious remedy lies in efficient prevention of aural suppuration and earlier treatment when it is present, so that the complete operation may be avoided. Into these points I need not enter, they are self-evident. I would, however, point out that the number of cases with discharging ears seen by me in the course of my inspections at the L.C.C., has diminished during the past 21 years by nearly 50 per cent., a striking evidence of improved conditions.

ON THE
PATHOGENESIS OF AVITAMINOSIS A

VITAMIN A AS THE ANTI-KERATINISING FACTOR

By Leslie J. Harris, D.Sc., Ph.D.
OF THE NUTRITIONAL LABORATORY, CAMBRIDGE

With sections in collaboration with

J. R. M. Innes, Ph.D.
OF THE INSTITUTE OF ANIMAL PATHOLOGY

AND

A. S. Griffith, M.D. Vict., Ph.D. Camb.
OF THE DEPARTMENT OF PATHOLOGY, CAMBRIDGE

nd presumably of value in combating all types of fections—i.e., that vitamin A is the anti-infective itamin in the wide sense in which vitamin C is the ntiscorbutic vitamin, vitamin D the antirachitic, or itamin B the anti-beriberi. Commercial vitamin-A reparations are advocated "for the treatment of epticæmias and acute infections" and claimed to 'increase the general immunity." The evidence ollected in the present paper is in support of the view hat the infections which occur in vitamin-A deficiency re of a quite special type, localised in origin, and ssociated with the keratinisation of mucous membrane, which is regarded as characteristic of the eficiency; and of the corollary that the anti-infective powers of the vitamin are similarly limited in scope.

Xerosis and cornification, or keratinisation, of epithelial tissues in vitamin-A deficiency has been described by Mori,[3] Wilson and DuBois,[4] and Wolbach and Howe.[5] But whereas Wolbach and Howe regard the epithelial keratinisation as the primary lesion, Yudkin and Lambert[6] conclude that the keratinisation is secondary to the inflammatory process and infection, and Wason[7] similarly supposes the xerotic changes in the cornea to be secondary to and not the cause of the infection. Goldblatt and Benischeck[8] believe that infection might be either coincident with or subsequent to the epithelial change, while Tyson and Smith[9] conclude that infection may occur in the absence of keratinisation. Further study of this aspect of the problem therefore seemed desirable.

It has been claimed that rats, a species it will be recalled normally highly resistant to tuberculosis, become susceptible when fed on a diet deficient in fat-soluble vitamins (attributed alternatively to vitamin A[10] or D[11]), or that they become sensitive to tuberculin shock under the same circumstances.[12] These conclusions would appear to support the theory that vitamin A has a real action in increasing immunity to pathogenic organisms, in addition to its function in maintaining the health of the mucous membrane. It was decided, therefore, to see whether confirmation could be obtained for this suggestion—with negative results, as will appear below.

Evidence from Past Work

If vitamin A possesses any generalised anti-infective action it is reasonable to seek for some change in immunological reactions in vitamin-deficient animals. All attempts in the past to show such a correlation have, however, yielded substantially negative results (examination having been made of: agglutinins, complement, amboceptor, precipitins, bacteriolysins, hæmolysins, and immunising power of vaccination). A second line of approach is to determine whether inoculation with suitable micro-organisms or toxins is more lethal to an animal on a diet low in vitamin A than to an animal on a normal diet. Several workers claim to have obtained indications of a positive effect of this kind. A serious difficulty of interpretation arises here however. It is obvious that an animal suffering from the double disability of toxæmia and vitamin deficiency is likely to fare worse than one suffering from either alone. That is, the effect may be merely additive, and indicate no genuine direct action of the vitamin upon resistance. In my opinion, the effects recorded in the literature have rarely, if ever, been sufficiently striking to dispose of this criticism. On the other hand, there is some evidence that when micro-organisms are fed per os there is a tendency to greater absorption, and hence more severe ill-effects, in vitamin-A deficient as compared with normal animals (see below); which accords with the theory that in vitamin-A deficiency the integrity of the mucous membrane breaks down and ceases to function as an efficient barrier.[13] This consideration suffices to account for the many recent experimental findings which would otherwise appear to indicate a general anti-infective action for the vitamin, and have, in fact, been so interpreted. Against this trend in recent conclusions we may recall that, as long ago as 1924, Cramer and Kingsbury[14] found that vitamin-A deficient rats were no more susceptible than normal rats when the micro-organisms were injected subcutaneously; while Topley, Greenwood, and Wilson[15] have reported that large amounts of vitamin A added to a normal diet fail to reduce the severity of epidemic infections in mice.

Clinically vitamin-A therapy has yielded negative results in trials as a prophylactic against respiratory infections[16] and common cold[17] in infants, or the incidence of common infections generally[18]; it had a doubtful value in treatment of pneumonia[19] and failed to increase streptococcal immunity in pregnant women as judged by the Dick test.[20] In puerperal sepsis the occurrence of infection at the mucous membrane may provide a rational basis for vitamin-A prophylaxis, but, as pointed out by Mellanby, the number of cases so far treated does not yet permit of any final conclusions as to its value, having regard to the great variability of prognosis of individual cases.[21] The same difficulties as to natural variations in virulence and mortality, and the relatively small number of cases treated, make it even more difficult to assess the results of vitamin-A therapy in puerperal septicæmia.

Development of Lesions of Avitaminosis A in Rats

(*With* Dr. J. R. M. INNES)

Our object in this side of the investigation was to observe the slowly developing lesions of a- or hypovitaminosis A, with the hope of throwing light on their earliest manifestation, and order of appearance, in particular, if possible, to determine whether the structural changes in epithelia appeared to precede the infections.

Large groups of rats (26 animals were used in the principal experiment) were put on a vitamin-A free diet, consisting of sugar, 60 parts; purified casein (Glaxo brand), 20 parts; hardened cotton-seed oil, 15 parts; marmite, 10 parts; salt mixture, 5 parts; with a daily supplement of Radiostol (vitamin D). In order to permit of a slow development of symptoms. a minimal provision of vitamin A (as red palm oil) was given once the animal had begun to lose weight, sufficient being allowed to prevent too early death or rapid loss in weight, but insufficient to enable good growth to be resumed. Representative animals were killed every few days, from 17 days after the beginning of the experiment, up to 90 days. After post-mortem examination the following tissues were prepared for histological examination by the usual routine methods: eye, tongue, submaxillary and sublingual glands, pharynx, œsophagus, trachea, lungs, stomach, intestines, liver, spleen, kidney, bladder, testes, and seminal vesicles (or uterus).

Perhaps the most important general observation was that in all instances where infection had occurred keratinisation of epithelium could without exception be detected, including generally in sites not far removed from the infection. It is important to note that the infections are of a highly distinctive character, apparently always originating in the neighbourhood of an epithelium. Thus small abscesses seen in the medulla of the kidney in the later stages appeared to have spread from the pelvis; infectious lesions in the lungs from the bronchi; and those in the tongue, from the surface of the mucous membrane. The probability that the infections are secondary to the structural changes in the epithelium which follow on vitamin-A deficiency seems obvious. But the hope that one might be able to demonstrate, in the group of animals taken as a whole, two definite stages, first keratinisation without infection, leading later to a secondary infection, was in general not realised.

It is true that in certain sites, notably in the sublingual (and submaxillary) glands, which are the seat of the most constant and characteristic lesions, the early condition is slight keratinisation (in the ducts) with little or no infection, and the later stages keratinisation accompanied by increasingly severe infection. Thus in one series of animals half way through a slowly developing vitamin-A deficiency, 5 animals in serial order showed slight keratinisation without infection, and the next 9 in order—the avitaminosis now reaching more advanced stages—showed definite infection. In many sites, however, no clear-cut division into two stages, keratinisation without infection and keratinisation giving rise to infection, could be demonstrated.

In general, keratinisation and infection both increased gradually and concurrently in severity. The failure to find two separate stages in the development of the avitaminosis, throughout the body as a whole and in the whole group of animals, may be attributed firstly to the irregular, almost haphazard, order in which the epithelia become keratinised in the different animals in the group, and second, to the fact that infection may sometimes supervene almost simultaneously with the first detectable keratinisation.

When above we are using for convenience the term "keratinisation," we have of course in mind not one single factor but a series of structural abnormalities seen in the epithelia, comprising xerosis, keratinisation, desquamation. Secreting epithelium loses its normal character and becomes converted into a stratified, keratinised, desquamating structure, or in the cases of tissue like the epithelium of the kidney pelvis, or tongue, a hyperplasia is concerned in bringing about an analogous condition. It is easy to understand how these changes would conduce to local infections, and account for the observed picture. The xerosed membrane being deprived of its normal secretion, micro-organisms are not retarded from settling on its surface; apart from the more physical, or flushing, action of the secretion, its natural antiseptic properties, ascribed to lysozyme, must also be borne in mind. Secondly, the accumulation of a profuse debris of desquamated cells along the surface of a membrane will tend to set up irritation and cause severe obstruction, particularly in narrowly enclosed areas. Good evidence of ducts becoming in fact choked in this way and so rendered liable to infection is found in the experimental pictures of the ducts of the tongue, of the sublingual glands, and of the bronchi; these are commonly seen to be filled with desquamated epithelial cells, distended and infected. The pelvis of the kidney among other sites showed a similar condition.

The fact that vitamin A given to an animal not too far advanced in the avitaminosis will cure the diseased epithelia, and at the same time restore the animal to normal health, is further evidence for regarding the epithelium as the essential point in the pathogenesis of the infection. The local infection is, clearly enough, due to fortuitous micro-organisms which would normally prove harmless. If the condition is allowed to develop far enough, a general septicæmia may ultimately supervene. This can be attributed, beyond much doubt, to absorption of such micro-organisms through the walls of the perverted membrane which is no longer able to serve as an efficient barrier. Blood cultures confirm this conclusion, and there is little in common with acute clinical infections by specific pathogenic organisms to suggest that any benefit is likely to accrue from their treatment by vitamin A.

Influence of Vitamin-A Deficiency on Tubercle Infection in Rats

(*With* Dr. A. S. GRIFFITH)

Two experiments were carried out, the first of a more general character, to test the suggestion that in vitamin-A deficiency rats lose their normally high resistance to tuberculous infection, and the second to examine more particularly the effects of the increased absorption of the micro-organism from the alimentary tract which, on the grounds of the theory adopted in this paper, it was anticipated might be seen in vitamin-A deficient animals.

Expt. 1.—A large group of rats was put on a vitamin-A deficient diet consisting of casein (Glaxo brand), 20 per cent.; rice starch, 60 per cent.; dried yeast, 15 per cent.; salt mixture, 5 per cent.; radiostol 1 drop per rat per day; and after depletion, 6 animals which showed typical severe xerophthalmia were selected for test. These were then instilled in both eyes (one eye only in the case of an animal which had one eye completely closed), and in addition fed by pipette with an emulsion of a culture of bovine tubercle bacilli. Three normal control rats, which had been on a similar diet, but containing vitamin A in the form of cod-liver oil, were treated identically at the same time. The vitamin-deficient group were kept in a state of hypovitaminosis A, being given occasionally minimal allowances of vitamin A, sufficient to protect them from early death, but not sufficient to promote good growth. (The amount so needed was determined from controls in a third group, uninfected, but vitamin A deficient.) The infected vitamin-A deficient animals died after periods ranging from 20 to 93 days, and the controls were killed on the 47th and 97th days. Results were assessed on the basis of the following: macroscopic observation on autopsy, microscopical examination of lung, and cultures derived from the submaxillary and mesenteric glands. A similar picture was found in both the infected groups, vitamin A deficient and normal, and resembled that seen in previous experience in normal rats, after the same period of time after inoculation. In the lungs no more than two or three small greyish foci at the most could be detected, and there was little or no microscopic evidence of tubercle, while the average number of colonies cultured from the submaxillary and mesenteric glands was similar for the vitamin A deficient and the normal group.

It was concluded that under the conditions of this test the vitamin-A deficient rats showed no greater susceptibility than normal rats to tuberculous infection.

Expt. 2.—This experiment differed principally from the foregoing in the particular that the rats were not infected by a single exhibition of the micro-organism, but were fed it continually by mouth during the time they were suffering from the vitamin-A deficiency, with the aim of procuring a greater degree of absorption through the abnormal mucosa.

The diets were similar to that described for the preceding experiment. During a period of six weeks groups of rats on the vitamin-A deficient and on the normal diets received on eight occasions, with their food, in doses of 10 c.cm., mixed sputum from patients with phthisis. Several rats died after 82 to 116 days, and the others were killed at from 112 to 119 days for comparison. A comparison of the number of colonies obtained from the mesenteric glands suggested the possibility that there had been a somewhat greater absorption of tubercle bacilli in the vitamin-A free group, than in the group on normal diet. No macroscopic tuberculous lesions were observed at autopsy in the mesenteric glands or in the organs, in rats on either vitamin-deficient or normal diet, and the failure to find bacilli in emulsions of the lungs indicated that there had been little if any dissemination of tubercle bacilli.

It was concluded therefore that absence of vitamin A from the diet had not lowered the resistance of this refractory species to any extent such as to allow the invading tubercle bacilli to produce macroscopic tuberculous lesions.

Summary and Conclusions

1. A study has been made of the development of the lesions of a- or hypo-vitaminosis A in rats. The metaplasia (or hyperplasia) and keratinisation of epithelium is confirmed, and its loss of normal structure and function regarded as the essential feature of the deficiency. The infections found in vitamin-A deficiency are of a special type, limited in origin to epithelial tissues, and not seen in the absence of neighbouring keratinisation. They appear, that is, to be attributable to the xerosis, deficient secretion of mucus, and desquamation (which may set up local irritation, and obstruction in ducts, &c.). With provision of vitamin A, the epithelium becomes normal again and the local infections disappear. If the avitaminosis is allowed to develop the local infections spread, and the destruction of the integrity of the epithelium is presumably responsible for absorption of the fortuitous infecting micro-

organisms (normally non-pathogenic), and septicæmia may result.

2. The claim that rats become susceptible to tuberculosis when depleted of vitamin A, which appears to support the theory of a generalised anti-infective action for the vitamin, could not be substantiated. When the bacillus was fed by mouth some evidence was obtained suggestive of increased absorption in vitamin-A deficient rats, but not of any lowered general resistance to the spread of tuberculous disease.

3. The existing data afford no basis for the belief that vitamin-A therapy is likely to be effective in combating acute general infections due to specific highly pathogenic micro-organisms, or in those clinical toxæmias and infectious diseases which are unassociated with the peculiar structural breakdown of epithelial tissue, and the attendant localised infection, which characterises the vitamin deficiency.

The importance of ensuring that diets are adequate in vitamin A cannot, of course, be gainsaid. But measurements by my colleague Dr. Thomas Moore, to be presented in a later paper, show that in various types of commonly occurring infections, terminated by death, there were often abundant vitamin-A reserves, so that any advantage to be derived from the administration of the vitamin in such cases, with the aim of rectifying a non-existing deficiency, would remain to be proved.

THE LONDON HOSPITAL.—At the quarterly court, Sir William Goschen, chairman of the hospital, said that, after conference with the medical and surgical staff, much headway had been made with a definite scheme for the provision of private wards for paying patients. The scheme would not to any considerable extent affect the existing accommodation for ordinary patients and would not entail any additional building. It was reported that the demand for the London Hospital catgut had increased to such an extent that the quarters devoted to its preparation have become entirely inadequate, and a spacious laboratory site has been taken in close proximity to the hospital. Although only £6000 has been obtained towards the complete scheme for a Students' Hostel, it is needed so urgently that it has been decided to start on a section of the building and to add to it as means permit. It is proposed to form a London Hospital League, with the out-patients for its nucleus.

ON THE QUANTITY OF VITAMIN A PRESENT IN THE HUMAN LIVER

BY L. K. WOLFF, M.D.

PROFESSOR OF HYGIENE IN THE UNIVERSITY OF UTRECHT, HOLLAND

THE experiments of Wilson[1] suggested to me that it would be of interest to study the vitamin-A reserves possessed by the population of Holland, as indicated by the Carr-Price values given by specimens of liver obtained in the course of post-mortem examinations. In January, 1929,[2,3] I published a preliminary report describing the examination of 242 specimens. Since that time the work has been continued, and in the present communication data obtained from 957 specimens will be reviewed.

METHOD OF RESEARCH

Previous work has shown that the liver is the storage place of vitamin A in the body. Hence we are enabled, by an examination of the liver, to learn the quantity of vitamin A in the whole body.

Specimens of liver (two pieces from different parts in most cases) were taken at post-mortems carried out in the Binnengasthuis, Amsterdam (Prof. W. M. de Vries), in the Wilhelminagasthuis, Amsterdam (Dr. Hammer), in the Pathological-Anatomical Laboratory, Utrecht (Prof. Josselin de Jong). The post-mortem for the Crown was carried out by Dr. Hulst, of Leiden. On arrival at the laboratory, the pieces were placed in an ice-chest, and examination begun as soon as possible. A special examination undertaken for this purpose showed that the quantity of vitamin A of the liver undergoes no change on decomposition of the tissues.

The vitamin was extracted by a process consisting essentially of trituration with anhydrous sodium sulphate, followed by Soxhlet-extraction with light petroleum. Control experiments proved that this method gives results almost identical with those given by the alkali digestion method used by Moore, and that the results given by duplicate pieces of liver are usually identical (if not an average is taken). The vitamin A was estimated by the Carr-Price antimony trichloride technique, using a Lovibond tintometer. For convenience of comparison values have been expressed in the blue units (b.u.) used by Moore.*

Besides vitamin A the liver also contains carotene, which also gives a blue colour in the antimony trichloride reaction. The quantity present, however, is usually negligibly small in comparison with the amount of vitamin.

Classification of Material

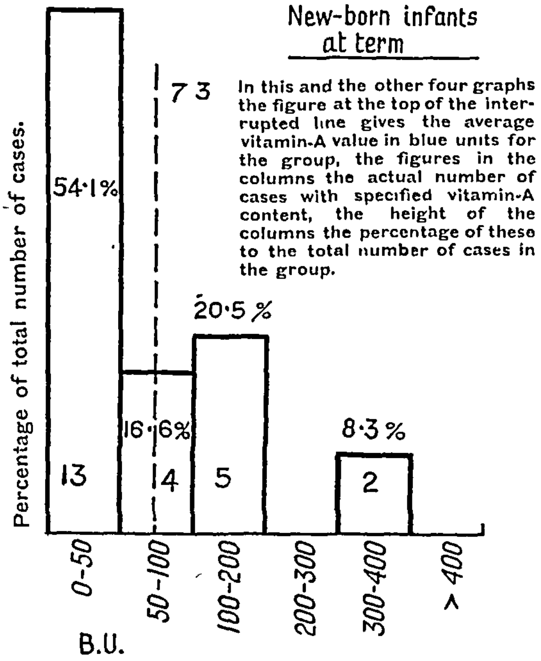
The post-mortem findings have been classified in four groups: (1) stillborn or died very shortly after birth; (2) killed by accident; (3) death through acute disease; and (4) death through a chronic disease.

The first group must be reviewed quite separately; the three others both together and apart. In the case of the last two groups the classification of the diagnosis has sometimes been somewhat arbitrary. As far as possible the principal cause of death has been chosen.

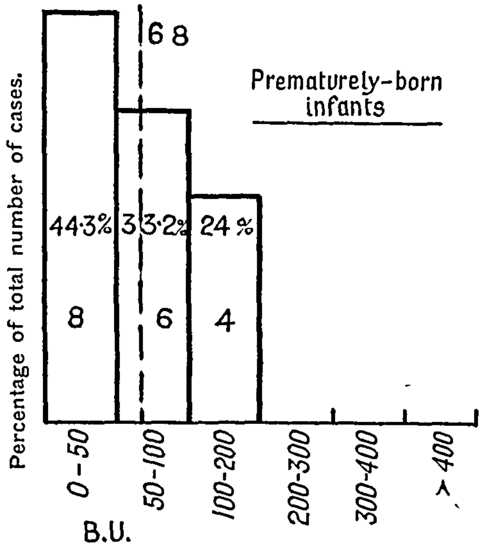
---

* The values given in this paper should actually be increased by 10 per cent. to be directly comparable with Moore's data, since in Mc[illegible] rrection has been made for the dilut[illegible] by the vitamin solution. This diverg[illegible] range of experimental error, and in any case is of little significance in comparing values which vary over wide ranges. The unit I used in my calculations was approximately 10 or 11 times greater than the unit of Moore; I had chosen that unit because it corresponds somewhere about the unit determined by experiments on rats (see O. Rosenheim: Biochem. Jour., 1927, xxi., 1331).

It will be clear that specimens taken at autopsy must be unsatisfactory material for acquiring a knowledge of the vitamin-A reserves of the normal individual, since three possible complications must be recognised: (1) that the quantity of vitamin A may have been reduced by disease; (2) that the quantity of vitamin A may have been increased by special diets; (3) mortality may be greater among those patients having a low reserve of vitamin A than among those having a high reserve. A better insight into the quantity of vitamin A of the normal individual will therefore be afforded by examining specimens from cases who have died as a result of accident; 78 accident cases have been examined. In addition, the category of acute diseases contains many cases which can be put on the same footing—e.g., acute hæmorrhage. To other acute diseases, of course, objection (3) may also apply to a considerable degree; that (1) and (2) play an important part here is less probable. In any case, considerable caution in drawing conclusions must be exercised. The difficulties outlined above can only be overcome by a very large number of determinations.

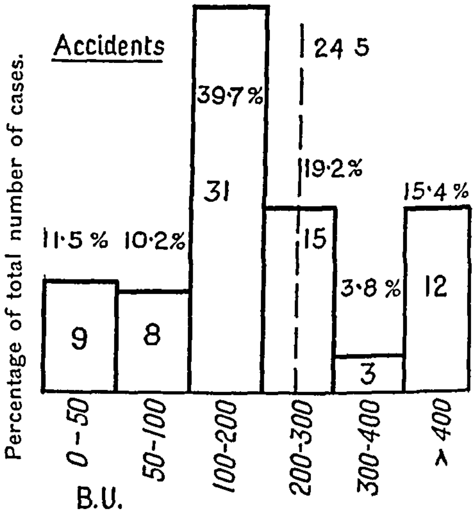


In this and the other four graphs the figure at the top of the interrupted line gives the average vitamin-A value in blue units for the group, the figures in the columns the actual number of cases with specified vitamin-A content, the height of the columns the percentage of these to the total number of cases in the group.



NEW-BORN CHILDREN

The material at my disposal was undoubtedly abnormal (Table I.). Of the 42 cases, 18 were prematurely born. Moreover, some of those born at the normal term were certainly pathological. Although a single child (surgical extraction) gave the relatively high value of 400 b.u. per gramme of liver, the average for the 42 children was only 70 b.u. For those born at the normal time the average was 73 b.u.; for those prematurely born 68 b.u. Among these two groups no fewer than 14 (9+5) had no perceptible quantity of vitamin A.



In general the average for infants was much lower than in the older people. It may be assumed that among the class of people whose children are born in hospital, most of the offspring come into the world deficient in vitamin A. We should certainly bear this in mind both when regulating the expectant mother's diet and the new-born infant's. As will later appear, we have reasons to assume that the expectant mother in Holland has but a small stock of vitamin A, a not inconsiderable portion of which she has to give up to the child.

TABLE I.—*New-born Infants*

Born at Term

	Cases.	Per cent.
0 b.u.	9	37·5
1– 50 „	4	16·6
51–100 „	4	16·6
101–200 „	5	20·5
Higher than 200 „	2	8·3
	24, Av. 73 b.u. per g. liver.	

Prematurely Born

	Cases.	Per cent.
0 b.u.	5	27·7
1– 50 „	3	16·6
51–100 „	6	33·2
101–200 „	4	24·0
	18, Av. 68 b.u. per g. liver.	

Total 42 cases, average 70 b.u.

ACCIDENTAL DEATH

Specimens from 78 cases of accidental death have been examined (Table II.). The average vitamin-A content amounted to 245 b.u., individual cases varying between 0 and 1210 b.u.

TABLE II.—*Accidental Death*

b.u.	Cases.	Per cent.	b.u.	Cases.	Per cent.
0– 50 ..	9 ..	11·5	200–300 ..	15 ..	19·2
50–100 ..	8 ..	10·2	300–400 ..	3 ..	3·8
100–200 ..	31 ..	39·7	400–960 ..	12 ..	15·4

If we assume that 50 b.u. signifies a very low reserve of vitamin, then we find 9 cases (11·5 per cent.) falling short of this standard. We find a relatively low average at the ages from 30–40 years; the small number of cases, however, makes this observation of questionable significance.

ACUTE DISEASES

Data obtained in cases which have been ill for a short time only may contribute towards obtaining an insight into the quantity of reserve of vitamin A possessed by normal individuals. We must not forget that in a number of cases the disease may have arisen just because the reserve of vitamin A was low. Thus a connexion between sepsis and a lack of vitamin A has been postulated by Mellanby. From the present results (Table III.), however, it would appear that most acute diseases bear no relation to low vitamin-A reserves, since the mean average of 225 b.u. is practically identical with that of accidents (245 b.u.).

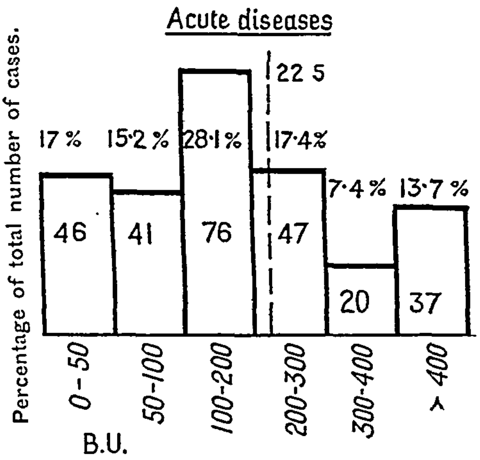


TABLE III.—*Acute Diseases*

b.u.	Cases.	Per cent.	b.u.	Cases.	Per cent.
0– 50..	46 ..	17·0	200– 300..	47 ..	17·4
50–100..	41 ..	15·2	300– 400..	20 ..	7·4
100–200..	76 ..	28·1	400–2400..	37 ..	13·7

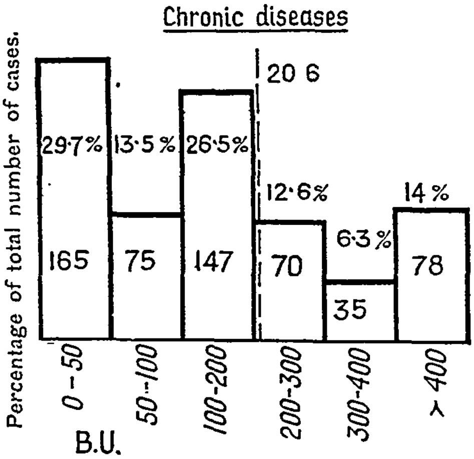
	Cases.	Average b.u.
Acute yellow liver atrophy	3	147
Poisoning	2	560
Embolism	7	126
Rupture of the uterus	3	75
Apoplexy	19	225
Heart-seizure	5	232
Hæmorrhage	4	190
Ileus, invagination	9	361
Peritonitis, acute appendix	28	250
Sepsis (average of 22 cases 182; one case had a value of 3520 b.u.) ..	23	327
Erysipelas	9	129
Pneumonia, lobar	47	211
Broncho-pneumonia	47	180
Measles	8	199
Whooping-cough	12	123
Diphtheria	13	382
Other infectious diseases	4	164
Otitis media, acute meningitis ..	19	250
Phlegmons, &c.	5	151
Total	267	225

Taking these results as a whole we find that 17 per cent. of the cases had reserves of less than 50 b.u. per g., or, in other words, that the food of about one-sixth of the population is partially deficient in vitamin A.

Individual acute diseases.—Results considerably below the average were found in 7 cases of embolism (126 b.u.), and in 3 cases of rupture of the uterus (73 b.u.). In general low values were observed in puerperal cases. Of the 7 lung embolisms, 2 were after parturition (124 and 45 b.u. respectively), 2 cases of sepsis puerperalis gave 80 and 164 b.u. In all, 7 cases gave an average of 126 b.u. This finding agrees with the results of experiments in the Utrecht Laboratory of Hygiene on the quantity of vitamin A in the blood, in which gravidæ and puerperæ had been characterised by a very low amount of vitamin A in the serum.

The cases of sepsis had an average above the mean average—viz., 327. One case among them, however, gave an exceptionally high value (3520 b.u.). If this case is omitted an average of 182 is obtained, which is slightly below the general average. The number of cases, however, is too small to draw a conclusion either for or against Mellanby's view that a low reserve of vitamin A predisposes to sepsis.

Cases under phlegmons had almost a normal average; whooping-cough cases gave rather low results. The rest of the acute infectious diseases had an average higher than the mean average; 13 cases of diphtheria in particular gave a very high average (382). On the whole the general average corresponds closely with that in the accident group.



CHRONIC DISEASES

Of cases falling in this group 570 have been examined (Table IV.). With regard to their classification, it has been impossible to avoid being arbitrary, but as far as possible the diagnosis of the cause which must be held responsible for death has been chosen.

In this group the mean average of 206 is but slightly lower than in the preceding groups. We find 165 cases (=29·7 per cent.) giving values of less than 50 b.u. This is double the percentage found in the other two categories, which may readily be explained by the unhealthy state of the patients.

Individual chronic diseases.—Attention may first be directed to the few diseases in which very low values have been found. Thus syphilis III. and IV. gave an average of 102 b.u. This low value may possibly be ascribed to the influence of liver changes, and it is noteworthy that six cases of cirrhosis of the liver gave a very low average (71 b.u.). These results lend support to the view that the liver is the site *of the conversion of carotene to vitamin A*, which has not yet been proved with certainty. In the second place it might be suggested that the storage power of the liver is reduced in diseases of this organ. Diseases of the kidneys (usually chronic nephritis) also have a low average (129 b.u.), the cause of which cannot as yet be stated.

TABLE IV.—*Chronic Diseases*

b.u.	Cases.	Per cent.	b.u.	Cases.	Per cent.
0– 50	165	29·7	200– 300	70	12·6
50–100	75	13·5	300– 400	35	6·3
100–200	147	26·5	400–1200	78	14·0

	Cases.	Average b.u.
Heart diseases	102	163
Malignant tumours	159	173
Tuberculosis of the lungs	66	200
Other forms of tuberculosis	30	242
Syphilis III. and IV.	33	102
Kidney diseases	54	129
Diabetes	25	484
Cerebral and spinal diseases	22	255
Prostate—hypertrophy	8	298
Leukæmia, chron. anæmia	12	192
Ulcus ventric. et duodeni	16	382
Lung gangrene	5	254
Enteric fever	3	11
Liver cirrhosis	6	71
Bronchiectasis	3	108
Emphysema	3	284
Exophthalmic goitre	5	350
Diverse chron. suppurations	8	215
Gangræna pedis	3	142
Spina bifida	2	100
Various	5	169
Total	570	206

An exceptionally low average (11 b.u.) was observed in three cases of enteric fever. The number of cases, however, was too small to justify conclusions.

Very high values were found in diabetes (484 b.u.), which may readily be explained by vegetable dieting. The high values in surgical and miliary tuberculosis were probably caused by the customary cod-liver oil therapeutics.

SUMMARY

Specimens of human liver have been collected from 957 cases at autopsy. The quantity of vitamin A per gramme of liver has been determined colorimetrically in each case. Table V. recapitulates the information already given.

TABLE V.—*Recapitulation*

	Cases.	Average b.u.
Accidents	78	245
Acute diseases	267	225
Chronic diseases	570	206
	915	228
New-born infants	42	70

Of the 915 cases :—

b.u.	Cases.	Per cent.	b.u.	Cases.	Per cent.
0– 50	220	24·2	200–300	132	14·5
50–100	124	13·6	300–400	58	6·4
100–200	254	27·9	400–higher	127	14·0

From data obtained upon cases killed by accident or dying from acute diseases, there is good reason to believe that 16 per cent. of the population of the Netherlands have definitely subnormal vitamin-A reserves. In the case of chronic diseases this proportion amounted to 24·2 per cent., which may indicate some connexion between certain chronic diseases and deficiency in vitamin A. Under the following headings, embolism, pregnancy, whooping-cough, syphilis III. and IV., chronic nephritis, and enteric fever, values considerably below the average were found. In cases of sepsis the divergence from the average was not so distinct. In view of the small numbers of cases examined in some diseases, however, the element of chance cannot be completely ruled out.

The vitamin-A reserves of the new-born, taken as a class, fell very much below the general average.

STUDY OF THE
NAIL-BED CAPILLARIES AND HISTAMINE RESPONSE IN RHEUMATISM

BY A. A. BISSET, M.D. ABERD.

AND

A. WOODMANSEY, M.Sc., A.I.C.

HON. CONSULTING CHEMIST, ROYAL BATH HOSPITAL, HARROGATE

THERE is now much evidence of the association of defective peripheral circulation with the rheumatic syndrome. The sensitivity of arthritics and fibrositics towards climatic change is traditional. Thomson and Gordon [1] speak of chilly sensations and bluish extremities and of susceptibility to cold and damp, signs of vasomotor instability. Attention has been directed by Pemberton [2] to evidence indicative of a disturbance in the circulation, particularly in capillary areas. The same author [3] shows that the lowered glucose tolerance in arthritis may be influenced by vasodilators, and in treatment means to increase the capillary flow are adopted. Simpson [4] proves by the oscillometer a definite spastic condition of the bloodvessels of the foot or finger in cases of arthritis. *Acta Rheumatologica*, the journal of the Ligue International contre le Rhumatisme [5] puts it thus: "All of us are convinced that the irregularities of the circulation of the blood in the skin are one of the essential factors in the causation and continuance of rheumatic conditions."

Visual observation of the capillaries was first recorded by Heuter.[6] Lombard [7] described the method of placing a drop of oil on the skin, focusing a strong light and using a low power of magnification. Since then several investigators have published diagrams and photographs, among which it is necessary to refer to the important work of Lewis.[8] Crawford and Rosenberger [9] used the cinematograph. Brown and Lamb [10] described simpler apparatus for the observation and photography of the capillaries using polarisers. Pemberton [11] found the capillary field of an arthritic to be markedly different from normal. Diagrams are given to show these differences.

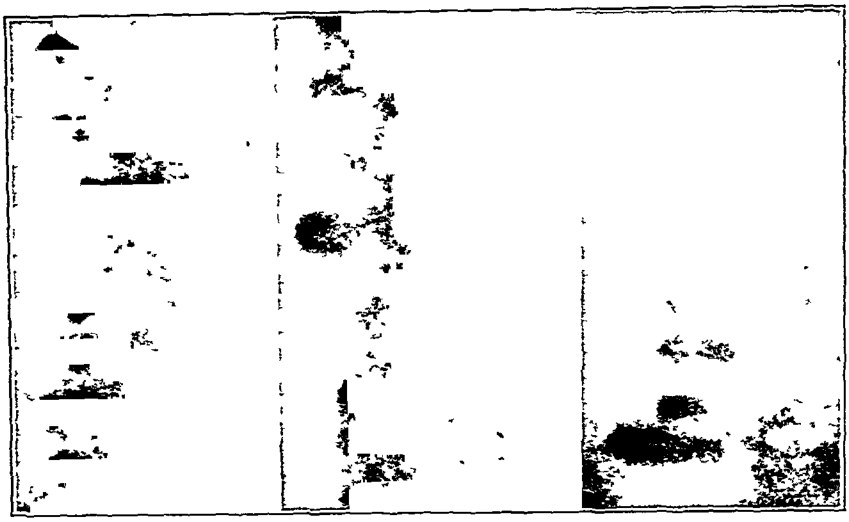
The present study of the capillaries of the nail-bed was made to determine what were the actual differences, if any, in form or number, in rheumatic cases as compared with normals, and relied largely on photographic methods. Improvised apparatus was first used in 1930 and successful photographs were obtained, but the arrangement was cumbersome. Later, with the apparatus supplied by Leitz, very satisfactory results were obtained. The magnification used was ×60 and the length of exposure half a second.

The nail-bed capillaries were chosen in this series of observations in preference to those of any other part of the body for convenience in rapid examination of patients with the Leitz apparatus, which is *only* adapted for this site; because the identical capillaries may easily be found for re-examination; and because the loops in shape and position readily lend themselves to measurement.

In order to find whether it was desirable to use any particular finger as a standard, observations were made on all the fingers of both hands with several subjects, but the appearances did not differ appreciably. The second or third finger was taken for examination in the following cases.

More than 100 cases of fibrositis and arthritis and 36 normals have been examined. Four pathological and three normal photographs are reproduced here. They are chosen not because they exaggerate the characteristics to be described but because they represent certain types of picture observed.

FIGS. 1 2 3



Photographs of nail-bed capillaries in three normal subjects. (×60.)

Normal A.—Male, 19 years. The loops are thick but without any appearance of stasis. There is a uniform and dense frontage of loops. All are curly, and the ratio of visible lengths in focus to diameter across the turn is about 3 : 1. (Fig. 1.)

Normal B.—Male, 36 years. Loops are thick, fairly numerous, and show indefinite outlines. This latter condition seems to be common to many normal capillary fields. A few of the loops are attenuated. (Fig. 2.)

Normal C.—Female, 34 years. Shows a preponderance of straight loops which, although indistinct, are short, and the field is well filled. (Fig. 3.)

The factors to be noted in a normal picture are, except the last, such as might be expected to promote an efficient blood-supply, viz.: (1) Uniform well-filled frontage of thick loops (average diameter—i.e., distance across—0·05–0·06 mm.). (2) Usually a large proportion of curled loops. (3) Loops are short—i.e., they ascend and descend quickly from the arterioles to the venules. (4) Frequently the thick epidermis prevents a well-defined picture. This may have some bearing on the relative insensibility of a healthy subject to climatic variations. In the normal picture there is usually a lack of clear outline of the individual capillaries.

CASE 1.—Female, 54 years. Diagnosis: fibrositis. In this the loops are separated so that only about half the normal number appear. The average diameter of a loop is about 0·03 mm. and the calibre of each is attenuated. About one-third are curly. (Fig. 4.)

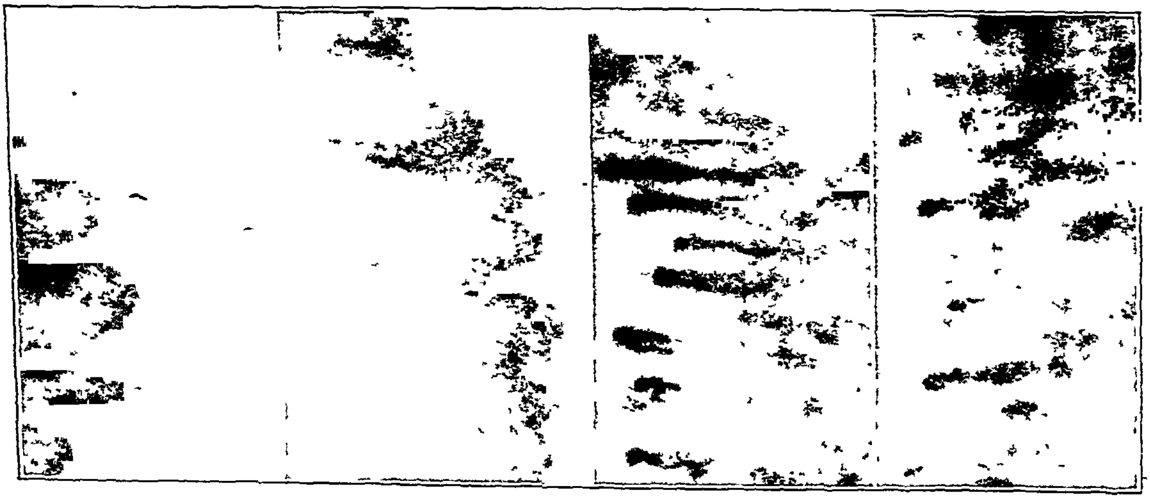
CASE 2.—Female, 41 years. Diagnosis: infective arthritis—indeterminate focus. These are typical fibrositic loops. The number per linear unit at one focal depth is low. The diameter of each is 0·03 mm., while the ratio of length to diameter is about 7 or 8 : 1. Discontinuities are visible, and are due to plasma spaces. The red cells, singly or in clumps, can be readily seen travelling round the loops in this type of picture. The calibre is fine, and twisted vessels are few in number. (Fig. 5.)

CASE 3.—Male, 68 years. Diagnosis: osteo-arthritis. There is an average number of loops but each vessel is very long and attenuated. (Fig. 6.)

CASE 4.—Female, 50 years. Diagnosis: fibrositis and arthritis. Another type is shown here. The glomerular appearance is normal, but the calibre is intensely fine. (Fig. 7.)

The rheumatic pictures show some or all of the

FIGS. 4 5 6 7



Photographs of nail bed capillaries in four arthritic subjects. (×60.)

following characters which (except the fourth) are indicative of circulatory deficiency: (1) a paucity of loops; (2) considerable attenuation present in all cases and consequent tendency to discontinuities; (3) usually (but not in all cases) long, straight loops parallel with and close to the surface, which permit (4) in general, a clear, crisp photograph. There appears no doubt that in most, if not all, cases of well-established rheumatic conditions the capillaries are in a spastic state, though we cannot yet affirm whether this state is specific to these conditions.

RESPONSE TO HISTAMINE

Recent research furnishes evidence that the capillaries are capable of changing their calibre in response to various impulses,[12] chemical, nervous, and physical. A sympathetic control operates indirectly through the hormonic mechanism. As examples of the chemical regulation, dilatation may be produced by histamine and constriction by adrenaline or pituitrin. In view of the constricted condition of the capillaries found in the rheumatic subjects examined, it was surmised that such cases might show variations in their response to histamine injections as compared with the normal reaction. Curtis Bain (personal communication) states that the typical flush seen in a normal case after an injection of histamine was in certain cases absent in young people with acute rheumatism.

Lewis [8] describes a simple method by which the skin reaction to histamine may be produced. A drop of dilute solution is placed on the forearm and pricked in superficially so as not to cause bleeding. The solution is then wiped off. After a time the capillaries in the vicinity are dilated, with the appearance of a pink flare and later of a small circular wheal. We adopted this procedure and the solution used was 1 : 2000 histamine acid phosphate.

		Av. of 11 : 50	Av. of 18 : 138	

Several of the "normals" showing higher values are subject to occasional symptoms of a rheumatic nature. One subject (180) states he has no rheumatism but is very sensitive to cold.

In certain cases the flare was so faint as to be inappreciable. Where this occurred the times were not recorded. In every subject, however, the wheal appeared after a measured time. In normals (Table I.) the flare appeared between 20 and 90 seconds (average of 11 cases, 50 seconds) whereas the wheal first became noticeable in from 90 to 240 seconds (average of 18 cases, 138 seconds). Similarly in pathological subjects (Table II.) the flare appeared between the same limits (average of 18 cases, 53 seconds), and the wheal between 80 and 240 seconds (average of 23 cases, 167 seconds). Thus in the rheumatic patients examined the superficial vessels were somewhat less sensitive to the chemical substance causing dilatation. The great variations observed in both normals and abnormals make it desirable that many more tests should be made to confirm such an important finding.

* Allergic.

One of the aims of treatment of rheumatic cases is to bring about an increase of skin function, which might reasonably be supposed to be associated with greater sensitivity towards a dilator substance. Ten cases at the Royal Bath Hospital were tested for histamine response upon entering and again just before leaving the hospital after a three-weeks' treatment (Table III.). The point at which the flare just appeared was, under the conditions of experiment, so difficult to determine accurately that the times were disregarded. The appearance of the wheal, however, was more definite. In five subjects there was little or no difference in the time taken by the wheal to appear, but in the other five a distinct

		Aver. 200	164

In the first five subjects there was little or no difference in susceptibility to histamine after treatment. In the second five subjects there was a distinct increase in susceptibility.

reduction of the time of response was observed. The averages were 200 seconds before treatment as against 164 seconds after treatment.

A further study may logically be directed to determine possible differences in purely infective and non-infective cases, and the existence of a hypothetical constrictor substance. It should also elucidate the effects of spa and other remedial measures more fully in terms of capillary physiology.

SUMMARY

The nail-bed capillaries of normals and rheumatic patients have been compared by photographic methods. Well-marked differences have been found and described.

The normal skin is slightly more responsive to the histamine test than the pathological cases examined.

An increase of skin sensitivity to histamine has been found in a number of cases after spa treatment.

We desire to thank Prof. B. A. McSwiney of the University of Leeds for helpful criticisms and advice, and the honorary medical staff of the Royal Bath Hospital for the provision of some of the cases.

Clinical and Laboratory Notes

SIGNIFICANCE OF "ANNULAR SHADOWS" IN RADIOGRAMS OF THE CHEST

BY JOSEPH SOWERBUTTS, M.B. CAMB.
HOUSE PHYSICIAN, ST. THOMAS'S HOSPITAL

SOME fifteen years ago, as a result of improvements in radiological technique, attention was first drawn to what seemed to be a type of cavity different from that usually seen. The ordinary tuberculous cavity usually appears in a severely affected area; it has an irregular outline, though not of necessity a definite visible wall, and is more transparent than the surrounding tissue.

The new type of cavity, the subject of this paper, differed in important respects. Its appearance (see Figure) was that of an opaque ring, regular in outline, of a more or less uniform thickness of from one-sixteenth to one-third of an inch, enclosing a circular or oval space from one to three inches in diameter. In addition, it was noticed that there was neither increased opacity of the lung immediately outside the ring, nor, necessarily, increased translucency within it. Clinicians, moreover, began to point out that these "annular shadows" differed considerably from the ordinary cavities, both as regards the accompanying symptoms and as regards the physical signs they produced.

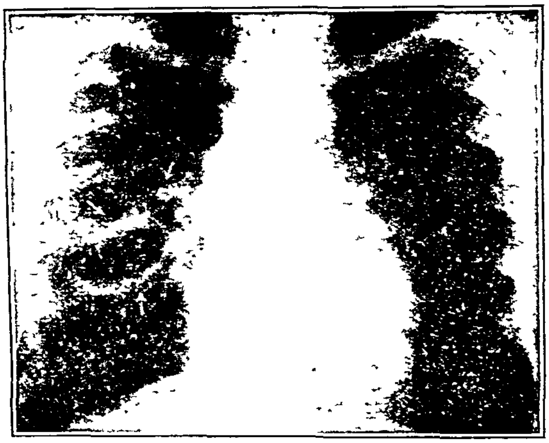
As regards the symptoms, opinions were somewhat at variance, much depending upon the extent of the associated disease, but it was generally agreed that these shadows might enlarge markedly, and yet the patient might display no symptoms of any kind. As regards the signs, however, observers at least have always been agreed: it is the rule for these shadows to produce no physical signs.

Clinicians having pointed out the distinctions between annular shadows and the ordinary cavities, various suggestions were put forward as to the probable pathogenesis of the former. The following theories were advanced:—

(1) That they were air pockets in the pleura in the region of the interlobar fissures.
(2) That they were localised pneumothoraces.
(3) That they were "pleural rings"—a term used by Amberson to indicate circular adhesions of the visceral and parietal layers of the pleural.
(4) That they were true tuberculous cavities.

These theories were considered by many observers to be quite inadequate to explain all the phenomena, but it was not until 1930 that any new hypothesis was put forward. Mitchell[1] then suggested an entirely original explanation. He considered that the shadows ought to be renamed "air-cysts" because they contained encysted air, and that their mode of origin was as follows:—

> "A small bronchus or bronchiole, weakened by disease and strained by coughing, becomes perforated and allows air to escape into the connective tissues of the lung. It does not become an interstitial emphysema, but a single bubble of air."



The typical appearance of annular shadows.

He explained the sudden enlargement of these air-cysts on the principle of the Bramah press, the pressure in the bronchial perforation during coughing producing a high pressure in the cyst. The ring shadow is produced by the compressed tissues constituting the cyst wall. Mitchell further stated that he had never known an air-cyst to be detected by clinical methods: no amphoric or cavernous breathing was present, and the percussion note differed little or not at all from that of the surrounding lung. If the perforation in the bronchus healed, the encysted air became absorbed, the compressed tissues re-expanded, and the ring disappeared, leaving no trace in the radiogram.

The following case is of interest, because it illustrates the inadequacies of the previous theories, while Mitchell's theory would seem to be capable of explaining the majority of the observed facts.

A girl, aged 18, was first seen in October, 1929. She gave a history of five weeks' lassitude and cough; she had

---

[1] Mitchell: Proc. Tuberc. Assoc. Meeting, Oxford, Jan. 20th, 1930.

had one hæmoptysis. She had lost weight and was at that time 8 st. 9 lb. There was also dyspnœa on exertion.

Examination revealed the presence of moderately extensive tuberculosis in the upper zone of the right lung, and she was sent to a sanatorium, where an artificial pneumothorax was induced on the right side.

She returned to St. Thomas's Hospital in July, 1930, much improved. Her weight was 9 st. 4 lb., and she was free from cough or other symptoms. An X ray film showed the right lung to be moderately collapsed, with apical adhesions. Artificial pneumothorax treatment was continued and the patient remained symptomless and apyrexial. X ray photographs were taken at three-monthly intervals and these showed the rapid development of an annular shadow in the collapsed lung. During the whole of this time the patient remained free from symptoms and was gaining weight steadily. Moreover, her sedimentation rate was normal, showing the absence of any marked degree of tissue breakdown.

In addition, a careful examination of the X ray films taken during this time showed that the position of the annular shadow had changed with the collapsing lung; furthermore, it could be seen in both the anterolateral and oblique views, and it caused "bulging" of the edge of the lungs in the anteroposterior film.

If the previous theories of the origin of an annular shadow are considered in the light of the above case, it will be seen that those which maintain its pleural origin are inadequate to account for the facts; thus it will be seen that annular shadows are not accounted for by: (1) pleural rings; (2) localised pneumothoraces; or (3) air pockets in the region of the interlobar fissures. The remaining hypotheses are the "true cavity" theory and Mitchell's view. Now, had this shadow been a true enlarging tuberculous cavity, one would have expected at least a cough with sputum, probably a rise of temperature and a loss of weight, and a sedimentation curve outside normal limits. None of these were present, and the rapid disappearance of the shadow which followed lends additional support to the view that it was not produced by a true cavity.

Clinical and radiological evidence would seem therefore to support Mitchell's air-cyst theory; but as yet the existence of these air-cysts has not been recognised by pathologists. A word may perhaps be said upon this point: a recent cyst would probably pass unnoticed, for it would collapse immediately upon section. An older cyst, in which, perhaps, tuberculous infection had supervened, would be expected to appear as a spherical cavity, with a soft wall covered by recent necrotic material; this type of cavity can be seen at times and differs markedly from the common type of spherical cavity which has a smooth, firm, and fibrotic wall. It is possible therefore that careful work by pathologists would prove the significance of annular shadows as determined by clinician and radiologist.

I am indebted to Dr. G. T. Hebert for his permission to publish this case.

POST-OPERATIVE HÆMORRHAGE IN NOSE AND THROAT OPERATIONS

TREATMENT WITH CLAUDEN

By W. S. Thacker Neville, M.D. Dub.,
F.R.C.S. Edin.
AURIST AND LARYNGOLOGIST TO THE GENERAL HOSPITAL, DARLINGTON

Hæmorrhage after operations on the nose is comparatively rare, since packing for 24 hours with such gauzes as Iodoform-styphnon or those prepared with adrenaline or bismuth usually suffices to prevent it. There are two ways of removing such a packing.

If hæmorrhage is expected then the best way is not to remove all the gauze at once, but rather to remove only the length which presents dark, dry blood. Once a piece covered with red, moist blood presents itself one ceases to withdraw the gauze. In this way, beginning 24 hours after the operation, the removal may be spread over 12 to 24 hours. If possible, however, it is better to remove all the gauze after 24 hours, for a tight packing left in the nose may cause local sloughing of the septum and a perforation or may result in otitis media. This last complication is improbable within 48 hours if an antiseptic gauze is employed.

The gradual removal or the complete removal of the gauze may be more painful than the operation itself and so I always anæsthetise the patient with a mixture of 2–3 c.cm. of ethyl chloride and 4 c.cm. of ether in an ethyl chloride inhaler before I proceed to remove it in one piece. This anæsthetic is the one I usually employ for tonsillectomy performed on children with Popper's guillotine or in a case requiring paracentesis of the tympanic membrane. In a case of tonsillectomy I allow the child to take 40–50 inhalations, but in removing a nasal plug from an adult 20 inhalations are ample, for only a momentary anæsthesia is required.

If there is nasal bleeding after removing the plug I order hæmostatic serum and large doses of sodium bicarbonate, whilst locally the nurse inserts a small plug of cotton-wool soaked in Clauden. Of all the styptics I have tried, clauden, which is an extract of lung tissue, is the most efficacious. It is made by the Luitpold works in Munich and may be injected or administered orally, as it is not affected by the digestive ferments of the stomach or intestine.

Oral administration is said to be suitable for sufferers from hæmophilia and preceding operations to increase the coagulability of the blood. In such cases four tablets (0·25 g. each) may be swallowed without water morning and evening before meals.

Clauden may be administered *intramuscularly* (10 c.cm. of a 2 per cent. solution three times a day). Thus given it may be employed on the day before, and one or two hours before an operation. It may also be given intravenously 10 to 20 c.cm. three times a day, even 40 c.cm. have been given intravenously with a total dose of 100 c.cm. in 48 hours.

If clauden is given *intravenously* it must be administered slowly from a syringe not sterilised in alcohol. Intravenous injection is contra-indicated in pronounced hypertension and in arterio-sclerosis, but in such cases it may be given intramuscularly.

Of intravenous and intramuscular injection I have no experience, for I have only employed this preparation orally and locally in nose and throat work where I have employed it in tablets, powder, and a 2 per cent. solution. It is applied as follows:—

In *post-operative tonsillar hæmorrhage*, the tongue is depressed wth an electrically-lit spatula, the clots are removed from the tonsillar fossa, and then a ball of cotton-wool soaked in clauden is pressed into the fossa for a few minutes. This arrests the hæmorrhage. I then employ the powdered clauden and with a powder blower insufflating the powder over the whole tonsillar fossa. With slight hæmorrhage insufflation of the powder suffices. As a matter of fact the nurses always have the solution and powder at hand and arrest the hæmorrhage before I arrive. In the post-operative treatment of gradual diathermic coagulation of the tonsils I have given the patient the powdered clauden and a powder blower, and at the first trace of hæmorrhage the patient insufflated clauden herself on to her tonsil. In such cases it is invaluable as it arrests the hæmorrhage and so allays the patient's fears and avoids the necessity of summoning a physician.

In two cases (mother and daughter) of *multiple angiomata* of the nasal mucous membrane the application of the fluid clauden by the patients themselves was sufficient to control the periodic hæmorrhages.

In a case of *epistaxis* from Kesselbach's area I arrest the hæmorrhage with cotton-wool soaked in the solution and then employ the cautery; or if the whole mucous membrane is oozing, as in the aged, I cocainise the nose and then pack it with gauze soaked in the solution. Finally, in such cases I tell the patient to carry a box of ampoules of the solution and cotton-wool in his pocket or handbag so that he may apply the remedy himself in case of hæmorrhage or where hæmorrhage may be expected.

However, if one meets a bleeder or hæmophilic these measures will not succeed.

Recently I did a Howarth radical frontal sinus operation on a man aged 29, all went well for eight days and he was due to leave the nursing home on the ninth day. On the eighth day a slight hæmorrhage occurred. It recurred in increasing amounts daily for four days in spite of packing the nose under an anæsthetic with clauden and administering it by mouth and injecting hæmostatic serum and peptone. On the fourth day Dr. Sinclair Miller gave a transfusion of 600 c.cm. citrated blood. This arrested the hæmorrhage for 36 hours, when another large hæmorrhage occurred. Dr. Miller then repeated the transfusion and following the second transfusion there was no serious hæmorrhage.

Before I knew the power that transfusion had in arresting hæmorrhage I operated on a patient aged 55, who had had profuse multiple nasal hæmorrhages. As he also had a deviated septum he was advised to have this straightened. For a week after the operation all was well, then after a nasal dressing profuse hæmorrhage set in, which was not controlled by the cautery. Finally I had to resort to the desperate measure of employing surgical diathermy; this was successful but resulted in continuous crusting and ozæna.

The object of this note is partly to draw attention to clauden as a local hæmostatic; but it is also written to show the dramatic effect of transfusion in arresting uncontrolled hæmorrhage.

PERINEAL TUMOUR IN AN INFANT

By C. E. M. Blumer, F.R.C.S. Edin.

SURGEON, STAFFORDSHIRE GENERAL INFIRMARY

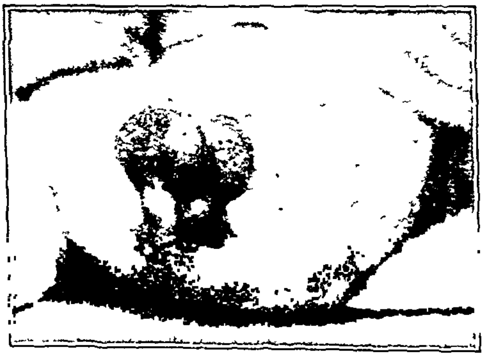
AND

T. Valentine Cooper, M.B. Lond.

ASSISTANT PATHOLOGIST, STAFFORDSHIRE COUNTY COUNCIL

A male baby was recently brought to hospital because of the presence of a tumour in the perineum. The child was a full-term normal delivery and there were no details in the family history worthy of note.

Fig. 1



The perineum showing divided scrotum and tumour.

On examination of the site of the lesion (Fig. 1) the following abnormalities were detected :—

The scrotum was divided, one testicle being present in each complete half. The penis and prepuce were set further back than normal and there was hypospadias. The anus was not in the midline, but was displaced to the right and slightly forwards. Situated on the left side of the perineum was a bright red nodule the size of a grape, with a semilunar sulcus at its base anteriorly. This sulcus was ¼ in. deep and ended blindly.

The mass was removed without difficulty and the child was sent home. Sections were made in the long axis of the nodule, which was considerably smaller after removal when the blood with which it was engorged had escaped.

Histologically the sections show this is a mass of striated muscle bundles (Fig. 3) in which are embedded several glandular ducts (Fig. 2). These ducts are lined with columnar epithelium which in some places is several layers thick. The basement membrane is nowhere transgressed. The covering of the tumour is composed of œdematous and hæmorrhagic connective tissue with no true epithelium over it.

Fig. 2

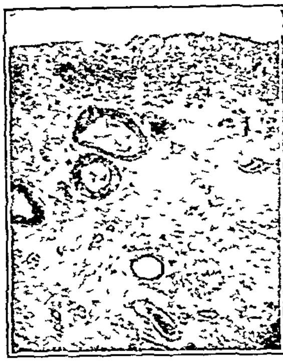


Fig. 3

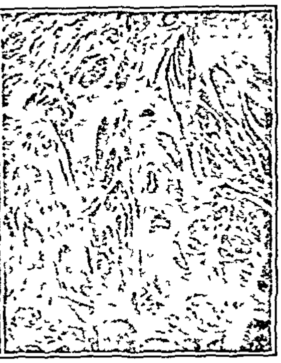

Fig. 2.—Section showing glandular ducts (× 60).
Fig. 3.—Section of tumour showing muscle bundles (× 60).

The pathological interpretation of these facts has been a source of considerable discussion, but we suggest that the glandular elements arose in connexion with the prostate or Cowper's glands and that the muscle present is derived from the superficial muscles of the pelvic floor. It has been contended that the striated muscle may be the gubernacular fibres of the internal oblique, but if this were the case, it seems to us improbable that the testicles would both have remained normal in position. Further, the malposition of the anal orifice appears to indicate a fundamental error in the embryonic evolution of the cloaca and uro-rectal septum. Since the prostate and Cowper's glands are both developed in connexion with that part of the cloaca [1] which forms the uro-genital sinus, we venture to postulate that a twist of the uro-rectal septum [2] has distorted the anal orifice so that it lies upwards [3] and to the right, while the prostatic and Cowper's elements are downwards and to the left.

The explanation of an abnormality such as the one described can at best be only conjectural, but we think this case worthy of record, partly because it is highly unusual, and partly in view of the difficulty of assessing the factors underlying its causation.

We have to thank Sir Arthur Keith for his interest and suggestions, and Dr. John Menton for his help in preparing the presentation of this case. The photograph of the child was taken by Dr. R. G. Johnson, and the two photomicrographs were made in conjunction with Mr. W. H. Fussell.

BRITISH MEDICAL ASSOCIATION

CENTENARY MEETING IN LONDON

SECTION OF MEDICINE

At a meeting of this section, with Sir THOMAS LEWIS, F.R.S., in the chair, a discussion on

Coronary Thrombosis

was opened by Dr. JOHN PARKINSON (London). Coronary thrombosis, he said, blocked the vessel affected, producing cardiac infarct of the area supplied; in addition it might precipitate intracardial thrombosis or pericarditis. The disease commonly occurred in a man over 40, who had often been in good health previously, but who might have been inconvenienced for months or years by anginal pain on undue exertion. He would suddenly begin to feel a dull, heavy pain in the chest, which he often fancied was indigestion, and which grew steadily more intense. He began to sweat, might vomit, and sometimes fainted. Often the pain extended through to the back and down the arms; it was continuous, but, unless he died, it began to abate after the lapse of two or three hours. On examination he was found to be pale and restless; the pulse was usually regular and moderately increased in frequency, but the rhythm was sometimes disturbed by fibrillation or heart-block. There was usually a rise of temperature a day or two later. The blood pressure fell shortly after the attack, which might be followed in a day or two by congestive heart failure and sometimes embolism. Coronary thrombosis was associated with arterio-sclerosis and was commoner in men than in women; an attack might precede the onset of fibrillation, flutter, or heart block. The lack of physical signs was apt to hinder recognition, which usually depended on the symptoms and history. The patient should be asked to map out the area of pain with his finger; sternal pain was a strong diagnostic point. Electrocardiography gave valuable evidence. Perforated gastric ulcer, acute cholecystitis, spontaneous pneumothorax, and pulmonary infarct must be excluded. If the patient weathered the first few days he was likely to recover, and a second attack was relatively infrequent. Morphine was the most important item in treatment at the outset; digitalis could be given as soon as signs of congestion appeared. The patient should be kept at rest in bed for a minimum period of six weeks, and in order to enforce this it was wise to explain the condition to him. When he was able to get up convalescence should last from three to six months. When he first described angina pectoris in 1768, Heberden said some attacks were short and others long; he was describing a composite picture of coronary thrombosis and the angina of effort. The conception of coronary thrombosis as a separate entity was of recent origin. The term angina pectoris might still be used to cover both conditions, though they were to be recognised as distinct. It was time to reconsider the prognosis in angina pectoris. Many patients recovered from an attack of coronary thrombosis, and patients with the angina of effort might live for many years. Angina of effort was incurable in so far as the coronary arteries were affected; but the process might be arrested or some degree of collateral circulation might be established to that section of the myocardium. The popular conception of angina pectoris applied to the disease in its severer forms, and a brighter view was justified. The patient would find life worth living and might live longer than was commonly supposed.

Prof. W. T. RITCHIE (Edinburgh) said that the patient with coronary thrombosis was seldom a woman, and was usually a man in the sixth or seventh decade of life. Valvular disease was rarely present; the blood pressure had sometimes been high for years, and sometimes the patient had suffered from previous attacks of anginal pain. Often he was seized with pain while at rest or in bed, sometimes following a physical or emotional strain. The pain might be xiphisternal, præcordial, or epigastric, and might radiate down the arms or into the neck. There was often fear of impending death and a sense of constriction of the chest. Usually the patient was afraid to move, but he might be restless, rocking himself to and fro; he was generally collapsed, livid, sweating, and groaning, and often retched or vomited. The pulse, if perceptible, was thready and rapid; the blood pressure had usually fallen, sometimes registering a systolic pressure as low as 60 mm. The pain might last 12 to 14 hours in spite of morphia injections. In rare cases there was no pain but only collapse, and sometimes dyspnœa. Auricular fibrillation, flutter, tachycardia, or auriculo-ventricular heart block might be present. In fulminating cases the patient might be gasping for breath or exhibit Cheyne-Stokes breathing; pulmonary œdema might develop, with copious, frothy, blood-stained sputum, bubbling râles being heard over the lungs. At autopsy it was often necessary to exhort the pathologist to seek minutely for the infarct. If the patient recovered he usually became mildly febrile a few days later, but the temperature subsided within three or four days. In about 10 per cent. of cases a pericardial rub was heard, which might vanish in a few hours or persist for several days. He had never found signs of pericardial effusion. There was danger of recurrence in the first few weeks, and in his experience half the cases died in the first fortnight. About 5 per cent. appeared to recover, and in the remaining 45 per cent. there was danger of fibrillation, angina of effort, aneurysm of the heart, or progressive heart failure developing.

Sir THOMAS LEWIS (London) said there was no distinction between the character of the pain in angina pectoris and in coronary thrombosis; the distinction lay in the duration of the pain. In the angina of effort pain ceased when the effort ended; in coronary thrombosis it lasted for hours or days. Parry had attributed anginal pain to ischæmia of the cardiac muscle. Burn had drawn attention to the resemblance between the pain of angina and the pain in a limb deprived of blood. Evidence had been collected to show that the pain was due to the accumulation of metabolites acting upon the sensory nerve-endings in the ischæmic muscle. He suggested that a similar picture was true in the case of the heart; if a vessel was narrowed, pain developed when the heart was pressed to do more work than it was accustomed to do. The pain was not spasmodic or stabbing, but continuous. This conception of the condition explained why amyl nitrite gave relief in the angina of effort but not in coronary thrombosis; amyl nitrite could open up the narrowed vessel but not the occluded one. It also explained why angina of effort might disappear after an attack of coronary thrombosis: the narrowed artery became permanently occluded, and after recovery from the attack of thrombosis no longer gave rise to pain.

Prof. W. E. **Hume** (Newcastle-on-Tyne) said that it was difficult to make an immediate diagnosis between coronary thrombosis and the angina of effort, as pain and collapse were the chief symptoms in both. The picture was much more alarming in coronary thrombosis than in angina of effort; the patient was livid and collapse was marked. Nitrites gave no relief and might do harm; repeated doses of morphia were necessary to control the pain. Shock and collapse might form the dominant picture with little complaint of pain. Or there might be symptoms of acute pulmonary œdema with frothy blood-stained sputum and fine crepitations in the lungs; a pericardial rub was sometimes heard. The appearance of the patient might sometimes suggest pneumonia, but the pain was not increased by deep breathing and the temperature was not high enough. The diagnosis sometimes had to be made from gall-bladder disease. It must be remembered that some cases of toxic angina had been relieved by removal of a septic gall-bladder or appendix. An attack of coronary thrombosis, in which the liver was congested and tender, and the muscles in spasm over it, might easily be confused with disease of the gall-bladder, and early gross arrhythmia of the heart might save the patient from an unnecessary operation.

Dr. **Carey** F. **Coombs** (Bristol) said that in a series of 144 patients with coronary thrombosis, one-third died during the attack and one-third during the following year. Those over 70 bore the calamity less well than younger patients. On the whole the prognosis was worse if pericardial friction was heard. The pulse-rate was an unreliable sign and might remain normal till the fatal termination of a case. The pulse pressure was significant, and might sometimes fall to 25 per cent. or less of the systolic blood pressure, and such narrowness was an unfavourable sign; unfortunately the converse was not true—patients with a wide pulse pressure were not necessarily likely to recover. Rise in the pulse pressure and blood pressure were favourable signs. Complete rest and full doses of morphia were essential to treatment.

Dr. D. E. **Bedford** (London) said that the sign of most significance in the electrocardiogram of these patients was the opposed direction of the R—T segment in leads I. and III., and this was almost pathognomonic of coronary thrombosis. The T-waves began to be affected in the second week as a rule, and it was common to find some return to normal in the first six months. Other forms of curve might be found, however, and a normal curve did not exclude a diagnosis of coronary thrombosis.

Prof. **John Hay** (Liverpool) mentioned anomalous cases in which the patient might become unconscious for 10 to 20 minutes and convulsive movements might be present, leading to errors of diagnosis. Dyspnœa was often absent in coronary thrombosis, and diagnosis should not depend on it. The pain, besides being continuous, varied in intensity, waxing and waning. Vomiting and tenderness over the liver, especially when associated with rigidity of the right rectus, led to errors of diagnosis.

Dr. **John Oille** (Toronto) thought that many mild cases of angina pectoris were overlooked and might be going about undiagnosed. Recent work went to show that coronary thrombosis was engrafted on an inflammatory, not a degenerative lesion, and it was therefore worth while removing foci of infection in these patients. At autopsy old healed infarcts were sometimes found in the heart, suggesting that some cases were entirely symptomless. Heroin relieved pain better in some cases than morphia, and was less inclined to favour vomiting. After a severe attack the patient should be kept in bed at least 12 weeks.

Dr. **Jenner Hoskin** (London) thought that thrombosis might depend to some extent on increased viscosity of the blood, and treatment might possibly be directed towards lessening this. He had found venesection helpful where there was marked congestive heart failure.

Dr. E. **Stolkind** (London) said that in his view angina pectoris depended on several factors—namely, (1) chemical and toxic substances circulating in the blood; (2) the influence of the autonomic and vasomotor nervous systems; (3) stimuli from the nerve-endings in the heart and aorta. The attack was brought on by the interaction of these factors; the part contributed by any one factor might vary, provided their combined influence was sufficient to provoke an attack. He emphasised the importance in the treatment of prolonged rest, and low, almost salt-free diet given in seven or eight small meals daily.

Prof. F. **Volhard** (Frankfort) referred to the importance of Sir Thomas Lewis's contribution to the question of pain, and the view that it had its origin from chemical substances produced in the ischæmic area of muscle. He agreed that a salt-free diet was of the first importance.

Prof. **Oliver** K. **Williamson** (Witwatersrand) read a paper on Internal Spasm as a Cause of Cerebral Cases of Transient Paralysis of Cerebral Origin. He described cases in which patients suffered from variable attacks of transient motor paralysis, with loss of consciousness and clonic spasm of the affected muscles; he suggested that they might be explained on the supposition of spasm of the cerebral arteries, similar to the spasm sometimes observed in branches of the retinal artery, and associated with loss of sight in the area supplied.

SECTION OF ANÆSTHETICS

At a meeting of this section when Dr. **Wesley Bourne** (Montreal) presided a discussion on the

Care of the Lungs in Anæsthesia

was opened by Dr. H. W. **Featherstone** (Birmingham). Formerly, he said, post-operative lung disorders were usually summed up as "ether bronchitis" or "ether pneumonia." Recent research had been devoted to post-operative massive collapse of the lung, and attention drawn to the therapeutic and prophylactic value of carbon dioxide diluted with air or oxygen. Ether vapour had an irritant effect on respiratory mucous membranes, but sound technique rendered this ill-effect negligible. Impurities such as ketones and peroxides were harmful and should be avoided by using only the purest ether. It was essential that the ether should be well vaporised, for a cold spray of ether droplets was particularly irritating. It was Shipway who first drew attention to the importance of giving ether vapour warmed, and his apparatus was most valuable. The proportion of ether vapour in the inhaled mixture should be as low as is practicable. In dogs massive doses of ether caused petechial hæmorrhage and pulmonary œdema; in lesser concentration narcotic drugs paralysed the vasomotor control of the blood-vessels of the lungs. It was common experience to find that the lungs of patients affected with subacute bronchitis a week or more before operation cleared up rapidly after administration of ether. Although the more serious risks of chloroform anæsthesia were due to damage to the cardiac nerves, heart muscle, and liver, the frequency of post-operative pneumonia suggested vasomotor disturbances. Nitrous oxide and ethylene were comparatively inert towards the respiratory epithelium; they were to be chosen in chest surgery and for the prolonged multiple operations of plastic surgery. Spinal analgesia had not proved a certain method of avoiding lung sequelæ; paralysis of some of the intercostal muscles possibly conduced to immobility of the lower lobes and pulmonary congestion. Marked lowering of blood pressure might reduce the resistance to infection. On several occasions within a few hours of intrathecal injection of a local analgesic he had seen a slight bronchitis develop into definite consolidation of the lungs. In spinal paraplegia involving the lower intercostal muscles carbon dioxide accumulated in the blood and oxygenation was deficient. Lesions of the dorsal region of the spinal cord were usually complicated by bronchitis or pneumonia. Splanchnic analgesia therefore by preventing reflex inhibition of the respiratory muscles should be a safeguard and many workers were satisfied that it was. Dr. Featherstone then briefly outlined the chief attributes of "closed," "open," and endotracheal ether administration.

Considering the effect of the operation, Dr. Featherstone held that posture was of little importance. The site of operation however might exert powerful influence on the state of the lungs. In diseases of the stomach, starvation or indigestion or delayed absorption of food might predispose to lung disease. The effects of malnutrition were shown by the high mortality-rate from post-operative pneumonia just after the war. Purgative and pre-operative starvation were to be avoided; rectal feeds of glucose and water were of value. Operative shock was a potent cause of lung disease; damage to tissues, loss of blood, and chilling of the body before and during operation were to be avoided as far as possible. Disturbance of metabolism and of the organs of defence occurred during anæsthesia; in a patient already suffering from poor general nutrition, from drug addiction, or from circulatory failure, special care was needed to spare the lungs from irritation and the body from toxic effects. Patients who had suffered from pneumonia during the year or two before a major operation were specially liable to post-operative pneumonia. The importance of avoiding anoxæmia must be borne in mind, and additional oxygen given to those whose respiratory exchange was embarrassed by deformity of the chest, paralysis of respiratory muscles, laryngeal obstruction, loss of function in part of the lungs from injury, emphysema, frothy excretion, or shallow breathing as the result of shock or overdose of anæsthetic. In the surgery of toxic goitre extra oxygen was a safeguard both during operation and recovery stage.

Massive collapse of the lungs after operation had been variously explained. Some believed that occlusion of bronchioles or a bronchus by inflammation, spasm, or secretion was followed by absorption of the imprisoned air and collapse of the affected area. Reflex disturbance of the vagus and sympathetic innervation of the lungs was held accountable by others. Others again attributed the condition to paralysis or inhibition of the respiratory muscles due to trauma or post-operative disturbance. Sir Charlton Briscoe believed that contraction of the crural portion of the diaphragm was diminished after an operation and deflation of the lower lobes of the lungs followed. His own opinion, said Dr. Featherstone, was that post-operative massive collapse was the result of several factors acting in conjunction; rigidity of the abdominal wall from pain and trauma, reflex inhibition of the diaphragm, congestion and œdema of quiescent lower lobes, swelling and spasm of bronchioles, inhalation of infective material, closure of bronchioles and absorption of air, all were concerned in its causation. The work of Band and Simson Hall, he said, seemed to show that viscid secretion, abolition of cough reflex, and limitation of respiratory movement were the chief factors.

Sir CHARLTON BRISCOE (London), who illustrated his views by a series of radiograms, said that pulmonary conditions were perhaps the commonest abnormalities arising after operations. Two points were of paramount importance. First, during anæsthesia by inhalation inspiratory efforts of great magnitude occurred, deeper than in dyspnœa, and almost as deep as in asphyxia. Secondly, after return to bed the patient was exhausted, all movements were painful, and those of respiration were limited to the minimum requirements. After abdominal operations full freedom of respiratory and other movements did not return for a week or ten days. Prolonged quiescence, post-operative or otherwise, with minimal respiratory needs, led to diminution of the size of the thoracic cavity, accentuated by the supine posture. He had shown that the shrinkage in the capacity of the thoracic cavity was due to elevation of the diaphragm into the chest, the lungs accommodating themselves to this shrinkage by deflation or de-aeration of the lower lobes, sometimes accompanied by over-distension of the upper. Deflation of the lower lobes constantly followed quiescence and minimal respiratory efforts, conditions which were present after abdominal operations in which the supine posture, pain on contraction of incised muscles, and depressed vitality were regular features. Normally this condition of deflation caused no symptoms, called for no examination, required and received no treatment. But it could not be neglected in the pathogenesis of post-operative pulmonary conditions. The activity of the lower lobes was in abeyance, but the blood-supply continued to exercise its function of nourishing the bronchial lining. Mucus was secreted; the cells of the bronchial walls and alveoli desquamated. It is quite common, he said, for patients after operation to accumulate mucus containing many and varied organisms in what might be called the "test tube" bronchus; absence of pyrexia and of leucocytes in the sputum showed that these bacteria were not pathogenic. A short non-productive but moist cough was present; expectoration was difficult in the deflated lung, for air did not get behind the sputum. The mucus was expectorated between the fifth and sixth day, and as a rule did not reaccumulate. If the bacteria became pathogenic the sputum was more abundant and purulent, it tended to reaccumulate, and pyrexia was present. More severe infection led to bronchial or lobar pneumonia. Pleurisy might accompany the latter. Massive collapse resulted from the onset of pleurisy in a patient in whom the lungs were deflated. The infection was probably of extra-pulmonary origin. It was remarkable how many of those who developed complications after operation had shown mild pyrexia the day or so before operation; 48 hours was the common incubation period for colds and bronchitis, and he had little doubt that infection about the time of the operation was helped by the deep inspirations produced by inhaling the anæsthetic.

It had been recommended to induce big respiratory efforts once or twice daily as a routine measure after operations, but the methods advocated were not without pain and discomfort. If the bronchi to the deflated lower lobes were not infected such expansion of the lungs would serve no purpose; if infection was present the contents of the bronchi would simply be more deeply inhaled. The contents of the bronchi could best be got rid of by deep inspiration, followed by short sharp expirations, the area of the incision being supported with a hand. A Burney Yeo inhaler, with some bland fluid, worn constantly was of assistance. Expectorants, stimulants, poultices, and so forth would be required if the infection spread further down. The pain and alarming symptoms of the massive collapse attack were relieved rapidly, as in other cases of pleurisy, by controlling the movement of the affected side by strapping or a spring belt. It was important to ensure that abdominal respiration was reacquired before getting up; neglect of this was a common cause of asthenia, breathlessness, and thoracic pains. Prophylaxis was all-important. The upper respiratory tract and teeth should be disinfected. Operation should be postponed if the patient felt chilled, if fever or increased pulse-rate was present. Any one of the team who was developing a cold should be sent away, and the patient should be protected from contact with infection during the first few hours after operation till the diminished immunity, local and general, produced by the anæsthetic had been repaired.

Dr. GEOFFREY MARSHALL (London) said that disease of the lungs might be a natural consequence of the illness for which the patient was subjected to operation, and that in many cases it would have occurred if there had been no operation or anæsthetic. Improved technique in anæsthesia could do little to prevent infection reaching the lungs via the blood stream, and still less to diminish the number of cases of infection of the lungs or the tragedies of pulmonary embolism. Primary responsibility for massive collapse of the lungs could not be attributed to the anæsthetic; there were, however, a large number of cases of bronchitis, broncho-pneumonia, and pulmonary abscess which might be prevented by more perfect technique. Except in great urgency a thorough overhaul should be made of the mouth, to eradicate open sepsis in the teeth and gums. Resistance was not built up by starvation and irritant purges. He had been greatly impressed during the war by the rapid recovery after extensive abdominal operations of soldiers whose chief preparation for operation had been a heavy meal of meat and vegetables. Incidentally there was a remarkable absence of vomiting during and after the anæsthetic. Damage to the lungs could be avoided by the choice of nitrous oxide or ethylene with oxygen, and the use of these anæsthetics would be more widespread if surgeons did not complain of insufficient muscular relaxation, particularly in abdominal surgery. But if general anæsthetics were administered in sufficient concentration to abolish the tone of a well-developed abdominal wall, they must do definite harm to the patient. If the abdominal muscles were to be paralysed this should be done by infiltrating them with a local anæsthetic. The procedure was easy, and could be carried out in two minutes by a practised surgeon.

The posture of the patient under an anæsthetic was of importance chiefly in relation to aspiration of secretion and foreign materials. Lung abscess after tonsillectomy was much commoner in America where the patient's head was raised during operations than in this country. He had seen several cases of lung abscess following extraction of teeth under nitrous oxide, the patient sitting up in a dental chair, and he was surprised this sequel was not more frequent. The importance of keeping the head below the level of the shoulders during operations on the upper respiratory passages was generally recognised, and there would be fewer post-operative pulmonary complications if this posture were employed in all operations. Posture was of special importance in anæsthetising patients known to be suffering from disease of the lungs. With bronchiectasis, fibroid lung, or chronic tuberculosis, the patient should lie on his side with the diseased lung underneath, in order to prevent infected secretions from spilling over into the comparatively healthy areas.

The discussion was continued by Dr. DAVID BOND, Dr. SIMSON HALL, Sir FRANCIS SHIPWAY, Dr. J. BLOMFIELD, and Dr. LANGTON HEWER.

Effect of Anæsthetics on the Liver

Dr. BOURNE read a paper, illustrated by graphs and diagrams, on the influence of anæsthetics on the liver. He showed experimental proof of the deleterious effects of heavy or prolonged chloroform inhalation, and the different times needed for recovery with different doses. Nitrous oxide and ethylene were shown to be innocuous provided that sufficient oxygen was given with them; the ill-effects of anoxæmia were demonstrated. Avertin also came passably through the tests; it had little effect in delaying recovery from chloroform.

In the discussion that followed, Dr. Z. MENNELL related a case in which he had seen symptoms identical with those of delayed chloroform poisoning in a patient who had had for the third time, at short intervals, an injection of avertin.—Sir FRANCIS SHIPWAY had used avertin in many cases of liver disease without mishap, and in 76 children who were given the drug he had seen no evidence whatever of liver disturbance.

SECTION OF DERMATOLOGY AND VENEREAL DISEASES

Dr. H. W. BARBER, the President of the section, took the chair at the discussion on the Principles of Diagnosis and the Modern Treatment of

Early Venereal Disease in Women

opened by Mr. J. JOHNSTON ABRAHAM (London), who confined his remarks to syphilis in pregnancy. A corollary to Colles's law was that the mother of a syphilitic child must be herself infected, though this was not generally admitted on the continent. The converse proposition that a syphilitic mother must bear a syphilitic child was certainly not true when the mother had been infected late in pregnancy. The clinical signs of early syphilis were few, and frequently tertiary lesions were the first to be noticed. The Wassermann reaction might become positive quite early, although 30 per cent. of congenital syphilitics were born of mothers with a negative reaction. All the manifestations of syphilis in women were milder and less common than in men, and the chief effects of the disease were shown not in the mothers, nor even in stillbirths nor abortions, but in their miserable children who lived. The virus did not die out, since syphilitic women could bear diseased children at any time, even to healthy consorts; nor did prolonged treatment eradicate the virus in women as it apparently might do in men. This made it subacute bronchitis a week or more before operation cleared up rapidly after administration of ether. Although the more serious risks of chloroform anæsthesia were due to damage to the cardiac nerves, heart muscle, and liver, the frequency of post-operative pneumonia suggested vasomotor disturbances. Nitrous oxide and ethylene were comparatively inert towards the respiratory epithelium; they were to be chosen in chest surgery and for the prolonged multiple operations of plastic surgery. Spinal analgesia had not proved a certain method of avoiding lung sequelæ; paralysis of some of the intercostal muscles possibly conduced to immobility of the lower lobes and pulmonary congestion. Marked lowering of blood pressure might reduce the resistance to infection. On several occasions within a few hours of intrathecal injection of a local analgesic he had seen a slight bronchitis develop into definite consolidation of the lungs. In spinal paraplegia involving the lower intercostal muscles carbon dioxide accumulated in the blood and oxygenation was deficient. Lesions of the dorsal region of the spinal cord were usually complicated by bronchitis or pneumonia. Splanchnic analgesia therefore by preventing reflex inhibition of the respiratory muscles should be a safeguard and many workers were satisfied that it was. Dr. Featherstone then briefly outlined the chief attributes of "closed," "open," and endotracheal ether administration.

Considering the effect of the operation, Dr. Featherstone held that posture was of little importance. The site of operation however might exert powerful influence on the state of the lungs. In diseases of the stomach, starvation or indigestion or delayed absorption of food might predispose to lung disease. The effects of malnutrition were shown by the high mortality-rate from post-operative pneumonia just after the war. Purgative and pre-operative starvation were to be avoided; rectal feeds of glucose and water were of value. Operative shock was a potent cause of lung disease; damage to tissues, loss of blood, and chilling of the body before and during operation were to be avoided as far as possible. Disturbance of metabolism and of the organs of defence occurred during anæsthesia; in a patient already suffering from poor general nutrition, from drug addiction, or from circulatory failure, special care was needed to spare the lungs from irritation and the body from toxic effects. Patients who had suffered from pneumonia during the year or two before a major operation were specially liable to post-operative pneumonia. The importance of avoiding anoxæmia must be borne in mind, and additional oxygen given to those whose respiratory exchange was embarrassed by deformity of the chest, paralysis of respiratory muscles, laryngeal obstruction, loss of function in part of the lungs from injury, emphysema, frothy excretion, or shallow breathing as the result of shock or overdose of anæsthetic. In the surgery of toxic goitre extra oxygen was a safeguard both during operation and recovery stage.

Massive collapse of the lungs after operation had been variously explained. Some believed that occlusion of bronchioles or a bronchus by inflammation, spasm, or secretion was followed by absorption of the imprisoned air and collapse of the affected area. Reflex disturbance of the vagus and sympathetic innervation of the lungs was held accountable by others. Others again attributed the condition to paralysis or inhibition of the respiratory muscles due to trauma or post-operative disturbance. Sir Charlton Briscoe believed that contraction of the crural portion of the diaphragm was diminished after an operation and deflation of the lower lobes of the lungs followed. His own opinion, said Dr. Featherstone, was that post-operative massive collapse was the result of several factors acting in conjunction; rigidity of the abdominal wall from pain and trauma, reflex inhibition of the diaphragm, congestion and œdema of quiescent lower lobes, swelling and spasm of bronchioles, inhalation of infective material, closure of bronchioles and absorption of air, all were concerned in its causation. The work of Band and Simson Hall, he said, seemed to show that viscid secretion, abolition of cough reflex, and limitation of respiratory movement were the chief factors.

Sir CHARLTON BRISCOE (London), who illustrated his views by a series of radiograms, said that pulmonary conditions were perhaps the commonest abnormalities arising after operations. Two points were of paramount importance. First, during anæsthesia by inhalation inspiratory efforts of great magnitude occurred, deeper than in dyspnœa, and almost as deep as in asphyxia. Secondly, after return *to bed the patient was exhausted, all movements* were painful, and those of respiration were limited to the minimum requirements. After abdominal operations full freedom of respiratory and other movements did not return for a week or ten days. Prolonged quiescence, post-operative or otherwise, with minimal respiratory needs, led to diminution of the size of the thoracic cavity, accentuated by the supine posture. He had shown that the shrinkage in the capacity of the thoracic cavity was due to elevation of the diaphragm into the chest, the lungs accommodating themselves to this shrinkage by deflation or de-aeration of the lower lobes, sometimes accompanied by over-distension of the upper. Deflation of the lower lobes constantly followed quiescence and minimal respiratory efforts, conditions which were present after abdominal operations in which the supine posture, pain on contraction of incised muscles, and depressed vitality were regular features. Normally this condition of deflation caused no symptoms, called for no examination, required and received no treatment. If the bacteria became pathogenic the sputum was more abundant and purulent, it tended to reaccumulate, and pyrexia was present. More severe infection led to bronchial or lobar pneumonia. Pleurisy might accompany the latter. Massive collapse resulted from the onset of pleurisy in a patient in whom the lungs were deflated. The infection was probably of extra-pulmonary origin. It was remarkable how many of those who developed complications after operation had shown mild pyrexia the day or so before operation; 48 hours was the common incubation period for colds and bronchitis, and he had little doubt that infection

SECTION OF OPHTHALMOLOGY

Sir JOHN PARSONS, F.R.S., the President, was in the chair at the session when a discussion was opened by Mr. R. FOSTER MOORE (London) on

Ocular Manifestations of Lesions of the Fifth Nerve

He pointed out that the Gasserian ganglion is the trophic centre for all the sensory branches of the trigeminal nerve. From each cell in the ganglion a single fibre arises, and this bifurcates, sending one branch centrally to the nucleus in the medulla, and one to be distributed to the tissues. Thus the ganglion might be involved by the spread of inflammation from middle-ear disease, or in a basic meningitis, or a tumour of the cerebello-pontine angle. It was of great importance in the production of headaches. A severe or prolonged stimulus might go beyond the cells which are in immediate organic continuity with the inflamed tissues, and might involve first one and then the opposite nucleus, till pain came to be referred to the whole territory of each nerve, and, overflowing further, might cause distant manifestations of a diffuse character. Herpes corneæ, with which dendritic and stellate corneal ulcers were closely allied, was little connected with herpes zoster ophthalmicus. There was a well-established connexion between herpes zoster and varicella, and some observers urged that shingles should be recognised as an infectious disease, and one likely to become a starting point for a chicken-pox epidemic. Herpes ophthalmicus was sometimes confused with erysipelas. Herpes zoster seemed to be an acute specific disease, and some product of it shows a selective activity for the ganglion cells. But an eruption indistinguishable from it might be caused by local trauma. The average age of onset was about 55, and it seemed to be most severe in the aged. Its first accompaniment was pain of a burning and lancinating character over an area which in three days became the seat of a rash. Its most important complications were those which involved the eye, including corneal affections, irido-cyclitis, ocular palsies, and optic atrophy. Intra-ocular complications occur in about 60 per cent. of the cases, and did not usually come on until the eruption had passed its most intense stage. Irido-cyclitis was a frequent complication, with or without corneal involvement, and glaucoma might eventuate. Metz had reported 50 cases of ocular palsies complicating herpes, the third nerve being involved in 74 per cent. of them. In most cases the nerve recovered. Optic atrophy was an important complication, and it would be interesting to know whether this is associated with some regular distribution of the rash.

The pathology of herpes zoster raised the question of antidromic impulses. In this disease the sequence of events was as follows: the acute infection causes an acute inflammation of the Gasserian ganglion, followed by pain referred along the fibres of the affected cells, and, four days later, by the appearance of the rash. Mr. Foster Moore had looked for the corneal nerve-fibres by means of the slit-lamp in 130 eyes, and had seen the fibres in 115 of them. Of neuroparalytic keratitis no satisfying explanation has yet been offered. Anæsthesia of the cornea alone did not suffice to cause ulceration of it, for if the cornea was properly protected by tarsorrhaphy, ulceration did not develop.

Dr. C. M. HINDS HOWELL (London) said that the eye received its sensory innervation by the ophthalmic division of the fifth cranial nerve. Afferent impulses passed by this route to the Gasserian ganglion, and thence by the central route to the pons. The fifth nerve-fibres were exposed to injury over a very wide area, and a constant result of damage to the fibres carrying afferent impulses from the eye was desensitisation of the globus oculi, with immediate loss of the corneal reflex. The chief danger from this was corneal ulceration. The question arose, what could be done to prevent such ulceration, and if it occurred, what methods were applicable to deal with it? The condition might be due to irritation of fibres, perhaps the antidromic fibres described by Bayliss in posterior roots. If ulceration of the cornea was due to peripheral nerve irritation, it should occur whether or not the lids are stitched. But careful protection of the eye seems to minimise, and any external trauma, even slight, to aggravate the tendency to inflammation and ulceration. Dr. Hinds Howell had never seen any affections of the deeper structures of the eye following injections of the ganglion with alcohol. Herpetic eruptions occurred occasionally, but he had not seen them in the distribution of the ophthalmic division. Malignant ulcers grew more rapidly in a desensitised area. A good method of treating the eye short of stitching the lids was to keep the upper lid carefully strapped down for two or three weeks, and then to allow the lids to open under an eye-shield, which should be worn at first indoors, later outdoors only, and finally abandoned. In the event of injection of conjunctival vessels, the lids should at once be stitched. He suggested that the tendency to ulceration in the cornea which has been desensitised by injury to the ganglion was not due to trauma alone, and there was no evidence to support the theory of a trophic nerve influence.

Mr. HUGH CAIRNS (London) said lesions of the eye produced by trigeminal nerve infections were practically limited to neuroparalytic keratitis following complete division of the trigeminal nerve at operation. Complete division of the sensory root had now been largely given up. The after-care of the conditions was very important. Suturing the lids should not be done without paring the edges. Even examination of the corneal reflex by students might be enough to precipitate corneal ulceration in the presence of herpes. Fluid from herpes zoster vesicles could transmit the affection, probably because the virus travelled down the nerve-fibres into the area of vesication and produced the vesicles locally.

Dr. RUSSELL BRAIN (London) said that occasionally in these cases there were symptoms of meningitis, especially with stiffness of the neck, and he had seen a fatal case of meningo-encephalitis due to herpes zoster. Lumbar puncture should be done as a therapeutic measure. The neurologist was often asked to treat the symptoms of ophthalmic zoster, and early and adequate treatment was found to do much to relieve the pain. In many cases the injection of 1 c.cm. of pituitary extract, as soon as the patient was seen, and repeated, if necessary, on the second day, might permanently relieve the pain. So also might the intravenous injection of 50 c.cm. of a 10 per cent. solution of sodium iodide. Another treatment was by convalescent serum, 10 per cent. being injected subcutaneously. The question of X ray treatment should also be considered; no risk attended X ray applications to the Gasserian ganglion in herpes zoster, but to be effective it should be carried out between the second and third weeks, not at the onset nor at the acute stage. At the stage essential that mothers should receive adequate treatment during each succeeding pregnancy. The common opinion that pregnant women were intolerant of arsenic was erroneous. They could be given larger doses than virgins. Mr. Abraham always gave it in conjunction with mercury or bismuth. Mercury was not so well borne as bismuth, though its reputation during four centuries made him chary of neglecting it on that account alone.

Colonel L. W. HARRISON (London) welcomed this opportunity of appealing to the profession for the better diagnosis and treatment of acute gonorrhœa in the female. The beginnings of the affliction were mild, and women took little notice of leucorrhœa, which they knew could be due to many other causes. Nevertheless these discharges should all be examined, and examined thoroughly. Even stained smears failed to show gonococci in 25 per cent. of cases; smears should be supplemented by culture of the discharge, and by the complement-fixation test, which was accurate when properly carried out. The treatment of the disease was not a hopeless proposition if it were realised that the urethra and cervix could be infected as well as the vulva, and that such infection could only be diagnosed by direct examination. If the local inflammation were conscientiously treated, and the general resistance raised by vaccines, the chances of recovery were very great.

Dr. T. ANWYL DAVIES (London) discussed the early diagnosis of syphilis. By far the commonest sites for the chancre were the cervix and labia majora. Inguinal adenitis was associated with only 40 per cent. of vulval sores, and was very rare with other sites. When it did develop the glands were large and elastic. Chancres could be distinguished from erosions and other lesions by their smooth sharply defined edges, their bluish colour, and tendency to bleed and ooze serum, but it was always essential to find the spirochæte. Dr. Anwyl Davies described his course of treatment at the Whitechapel clinic. The first dose of arsenic was the largest, and subsequent doses were repeated twice a week with only a short rest between courses. By this means he considered that the spirochætes were taken at a disadvantage, and the patient continued tolerant of the drug.

Dr. E. W. ASSINDER (Birmingham) said that acute syphilis and gonorrhœa were easily cured, but both diseases in the chronic stages were very resistant. It was essential to treat an early syphilitic for at least two years, and during the course a weekly injection of mercury or bismuth should be given. He started with a large dose of N.A.B. (up to 0·6 g.), which he decreased subsequently. The presence of gram-negative intracellular cocci in a discharge was not always conclusive of gonorrhœal infection; he had observed these to lead to a false diagnosis in an epidemic of *B. coli* vaginitis in a girl's school. Cultures and the complement-fixation test should be used. Acute gonorrhœa should be treated by a thorough routine in which the raising of the patient's resistance by vaccines and general measures was the most important part. He only resorted to diathermy and the application of silver nitrate when the acute symptoms persisted after two months' treatment, and in such cases the use of a vaccine to produce a rigor was helpful.

Dr. MARGARET RORKE (London) quoted two cases illustrating the prognosis in children born of recently infected mothers. Both women had developed florid secondary syphilis early in pregnancy, both had been conscientiously treated, and had borne apparently healthy children, yet both children died and were proved at the post-mortem to be syphilitic. If, therefore, the mother was suspected of having been infected at the time of conception, the baby's treatment should be carried on after birth till adequate courses had been given. Dr. Rorke said that during pregnancy all vaginal discharges should be investigated, since they might be due to gonorrhœa, which was an important cause of late puerperal pyrexia, and chronic subinvolution of the uterus. She had frequently found chronic gonorrhœa in the mother to be the cause of vaginitis in the child.

Dr. DAVID LEES (Edinburgh) read a paper on the Prevention and Treatment of

Ophthalmia Neonatorum

He compared the still high incidence of the disease in Great Britain with its great rarity in Denmark, which he attributed to the good education of midwives and students in prophylaxis, and to its compulsory use after all births in that country. Failures and complications were due to errors of technique. Silver nitrate should never be used in a dilution of less than 1 per cent., and the eye should always be irrigated after this application. He had tried many bacterial products, used both locally and intravenously for the treatment of established cases, but had not been convinced of their value. The conditions of successful treatment were skilled attention of mother and child in a hospital, half-hourly irrigation of the eye, so that pus was never under tension in the conjunctival sac, and the occasional use of a non-irritating antiseptic.

Dr. P. B. MUMFORD (Manchester) read a paper called

Acne, a Symptom not a Disease

He quoted opinions that acne was due to invasion of the skin by superficial parasites, and described three cases to show how this invasion might be determined by such conditions as menstrual disorder, sedentary occupation, and general ill-health. He had made preliminary investigations into the physical peculiarities of a large number of girl operatives suffering from this symptom, which showed that it was common in persons with greasy skins and a poor circulation, especially when accompanied by constipation, menstrual disorders, or dental caries. He concluded that acne was not a local disease of the skin.

Dr. G. B. DOWLING read a paper on

Infective Eczemata of the Scalp

He described four ætiological groups, each of which had a characteristic age distribution. Infantile eczema was usually an infection of the "milk crust." Impetigo in children was liable to spread from lesions behind the ears, on the eyelids, or in the nose, to produce an acute weeping eczema which had a tendency to persist into adult life with chronic incurable blepharitis, sycosis, and periodical reinvasion of the scalp. *Fausse teigne* was a dry reaction to a mild streptococcal infection which should be distinguished from pityriasis capitis and ringworm. Adults were subject to a seborrhœic eczema in which staphylococci grew secondarily to an original monilia infection. This appeared most constantly on the temples and forehead and was accompanied by figured eczema on other parts of the body, which distinguished it from chronic impetiginous eczema with its history of previous attacks, and of blepharitis or post-auricular fissures.

The PRESIDENT emphasised the disablement caused by impetiginous eczema in adults. This originated in the poverty and squalor of their youth, and could only be cured by early and prolonged treatment under healthy conditions.

that the two modes of reaction can proceed simultaneously and thus give rise to clinical and histological pictures which may be in the highest degree confusing and apparently contradictory, for at the one end of the scale there are the purely inflammatory granulomata, at the other the indolent non-reactive tomato tumours. The ætiology of this important group of diseases, which to some extent both in symptomatology and evolution resemble Hodgkin's disease, the lymphosarcomata (Sternberg-Paltauf) in the malignant forms, and the leukæmic dermatoses in the benign or granulomatous types, is still a matter of speculation. The infective theory predominates. Some authorities, in view of the completely anergic results of tuberculin injections in these cases and by analogy with the similar results in granulomata of accepted tuberculous ætiology and similar histological structure, favour a tuberculous cause. But although many guinea-pigs have been inoculated no conclusive result has ever been obtained, and it seems clear that the actual cause still escapes us. If it were to be found it might have an important bearing on attempts to elucidate the problem of cancer.

---

1. A Text-book of Organic Chemistry

Second edition. By Dr. JULIUS SCHMIDT, Professor of Chemistry in the Technische Hochschule, Stuttgart. English edition by H. GORDON RULE, Ph.D., D.Sc., Lecturer in Organic Chemistry, University of Edinburgh. London: Gurney and Jackson. 1932. Pp. 843. 25s.

2. Volumetric Analysis

By G. FOWLES, M.Sc., A.I.C. Assistant Master, Latymer Upper School, Hammersmith. London: G. Bell and Sons, Ltd. 1932. Pp. 202. 6s.

3. Chemistry, Life and Civilisation

A Popular Account of Modern Advances in Chemistry. By HUBERT T. S. BRITTON, D.Sc., D.I.C., F.I.C., Lecturer in Chemistry, University College of the South-west of England, Exeter. London: Chapman and Hall, Ltd. Pp. 248. 10s. 6*d*.

4. Applied Chemistry

A Practical Handbook for Students of Household Science and Public Health. Vol. II. *Foods.* Second edition. Revised. By C. KENNETH TINKLER, D.Sc., F.I.C., Professor of Chemistry in the University of London; and HELEN MASTERS, B.Sc., Head of the Domestic Science Department, Battersea Polytechnic. London: Crosby Lockwood and Son. 1932. Pp. 284. 15s.

1. Text-books on organic chemistry which aim at completeness tend to be uninspired and to amount to a recital of a long string of facts condensed in the minimum of space. This cannot be said of Prof. Schmidt's work which is readable and interesting. It has assumed rather large proportions and in bringing the second edition up to date it has been necessary to revise the whole text in order to avoid any appreciable increase in size. By curtailing the description of analytical methods in the general section space has been found for the discussion of recent work on conjugated systems, the electronic theory of valency, the mechanism of racemisation, epimerisation, spiro-compounds, the parachor, &c. In the systematic section are described recent work on the carbohydrates, terpenes, sterols, porphyrins, alkaloids, and proteins. More space has been allotted to the description of substances of biological importance than is usual in books on organic chemistry and the work may therefore be recommended as a text-book for honours students of chemistry and biochemistry as well as for graduates who wish to be informed in the advances made in knowledge on any branch of the subject since their student days.

2. Modest both in price and in appearance, Mr. Fowles's little book nevertheless contains a great deal of sound and useful information; it not only tells you what to do and how to do it, but why you do it. The author is in fact a believer in using volumetric analysis to illustrate the application of physical chemistry and we accordingly find illuminating articles from time to time on such subjects as the common ion effect, the solubility product, the mass action law, and the oxidation-reduction potential. The difficulty experienced by many readers in grasping the significance of the oxidation-reduction potential and its bearing upon biological problems is in the main due to a failure to appreciate that the phenomena of oxidation and reduction are really susceptible of electrical measurement. This difficulty at least should be largely removed by a perusal of the few pages here devoted to the subject; it is true that this is only an introductory account which stops short of mathematical formulæ, but so far as it goes it is clear and should form a sure foundation upon which to build a more advanced superstructure. Another feature of the book is the fact that it contains readable notes on accuracy in calibration of apparatus and weighing and of the influence of these factors on the results obtained; the all-important subject of indicators, too often briefly dismissed in other books on volumetric analysis, here receives adequate attention. This is a thoroughly practical little book.

3. Mr. Hubert Britton has set himself the task of sketching in simple language an outline of the many ramifications of chemistry. One chapter deals with glass, cement, and fire-fighting materials; four chapters are devoted to the applications of chemistry to vital problems including respiration and digestion. Others deal with clothing and paper, agriculture, metals and alloys, and lastly the generation of power. Mr. Britton has incorporated into one small book a wealth of miscellaneous information not easily accessible. Certain details are incorrect—such are the formula "considered to be a more satisfactory representation" for glucose on p. 109 and the number of hydrogen atoms in the formulæ given for palmitic acid on pp. 113 and 114, but these mistakes are not numerous or important. We are inclined to doubt whether the 32 pages devoted to some elementary principles of chemistry could possibly make the rest of the text intelligible to a reader who had no previous knowledge of the subject, but to one who already knows the elements of chemistry and to one who seeks ways in which to illustrate the applications of the sciences the book will prove helpful and stimulating.

4. This volume is designed to cover the food section of the course of applied chemistry which forms one of the subjects for the degree of B.Sc. Household Science of the University of London. The subject matter includes certain branches of the chemistry of food and the interpretation of analytical results; the ten chapters are devoted to milk, edible oils and fats, carbohydrate foods, raising agents, meat and meat extracts, vinegar and fruit juices, beverages, the preservation of food and poisonous metals in foods, the cooking of food, and the calorific value of foods. The book is written in a clear and practical

of post-herpetic neuralgia one had to consider interruption of the nerve by alcohol injection or by surgery. When the pain was in the infra-orbital region, especially if some sensibility remained, it was justifiable, and harmless, to try alcoholic injection of the supra-orbital nerve.

The PRESIDENT suggested that the beneficial effect of pituitary extract might have been due primarily to a chemical antagonism between the pituitary extract injected and the histamine caused by the lesion. The changes caused by the hormones were very resistant to treatment.

Mr. A. J. BALLANTYNE (Glasgow) said he had seen two cases in which ulcer of the cornea followed the giving of anti-typhoid vaccine. In certain affections of the eye, the cause was to be found in some other tissue or organ which received its innervation from the fifth, such as an iritis or keratitis, when the patient had a disease of nose, sinus, or teeth. He believed that in many cases there was a reflex vasomotor effect through the fifth nerve.

Mr. C. RUDD (Birmingham) said that of 15 cases of herpes zoster in his experience in which the Gasserian ganglion was injected with alcohol, 5 showed some ocular disturbance, 3 of them showing definite corneal ulceration, and 2 of these patients came with the pad rubbing the cornea. He found the use of a moist chamber over the eye very useful, rendering suture of the lids unnecessary; the condition healed up in two weeks. He suggested that possibly the products of degeneration of the cells and fibres following the injection had the same effect as a toxin, rendering the cornea liable to disintegration.

Mr. N. BISHOP HARMAN (London) referred to changes in the lens in association with herpes zoster or surgical interference with the fifth nerve. The ophthalmologist usually saw such cases after an attack, and in an appreciable proportion lesions of the lens could be found on the same side as the herpes lesion. Presumably the cause was a nutritive disturbance.

Mr. FRANK JULER (London) said he had not seen irido-cyclitis after alcohol injection of the Gasserian ganglion, but if the toxic products passed down the nerve one would expect such deleterious effects. It was dangerous not to advise that the eyes should be either strapped or sutured; even any septic condition present was not aggravated thereby, but tended to clear up under the bandage.

REVIEWS AND NOTICES OF BOOKS

Recent Advances in Obstetrics and Gynæcology

By ALECK BOURNE, M.B., F.R.C.S., and LESLIE WILLIAMS, M.D., F.R.C.S. Third edition. London: J. and A. Churchill. 1932. Pp. 418. 12*s.* 6*d.*

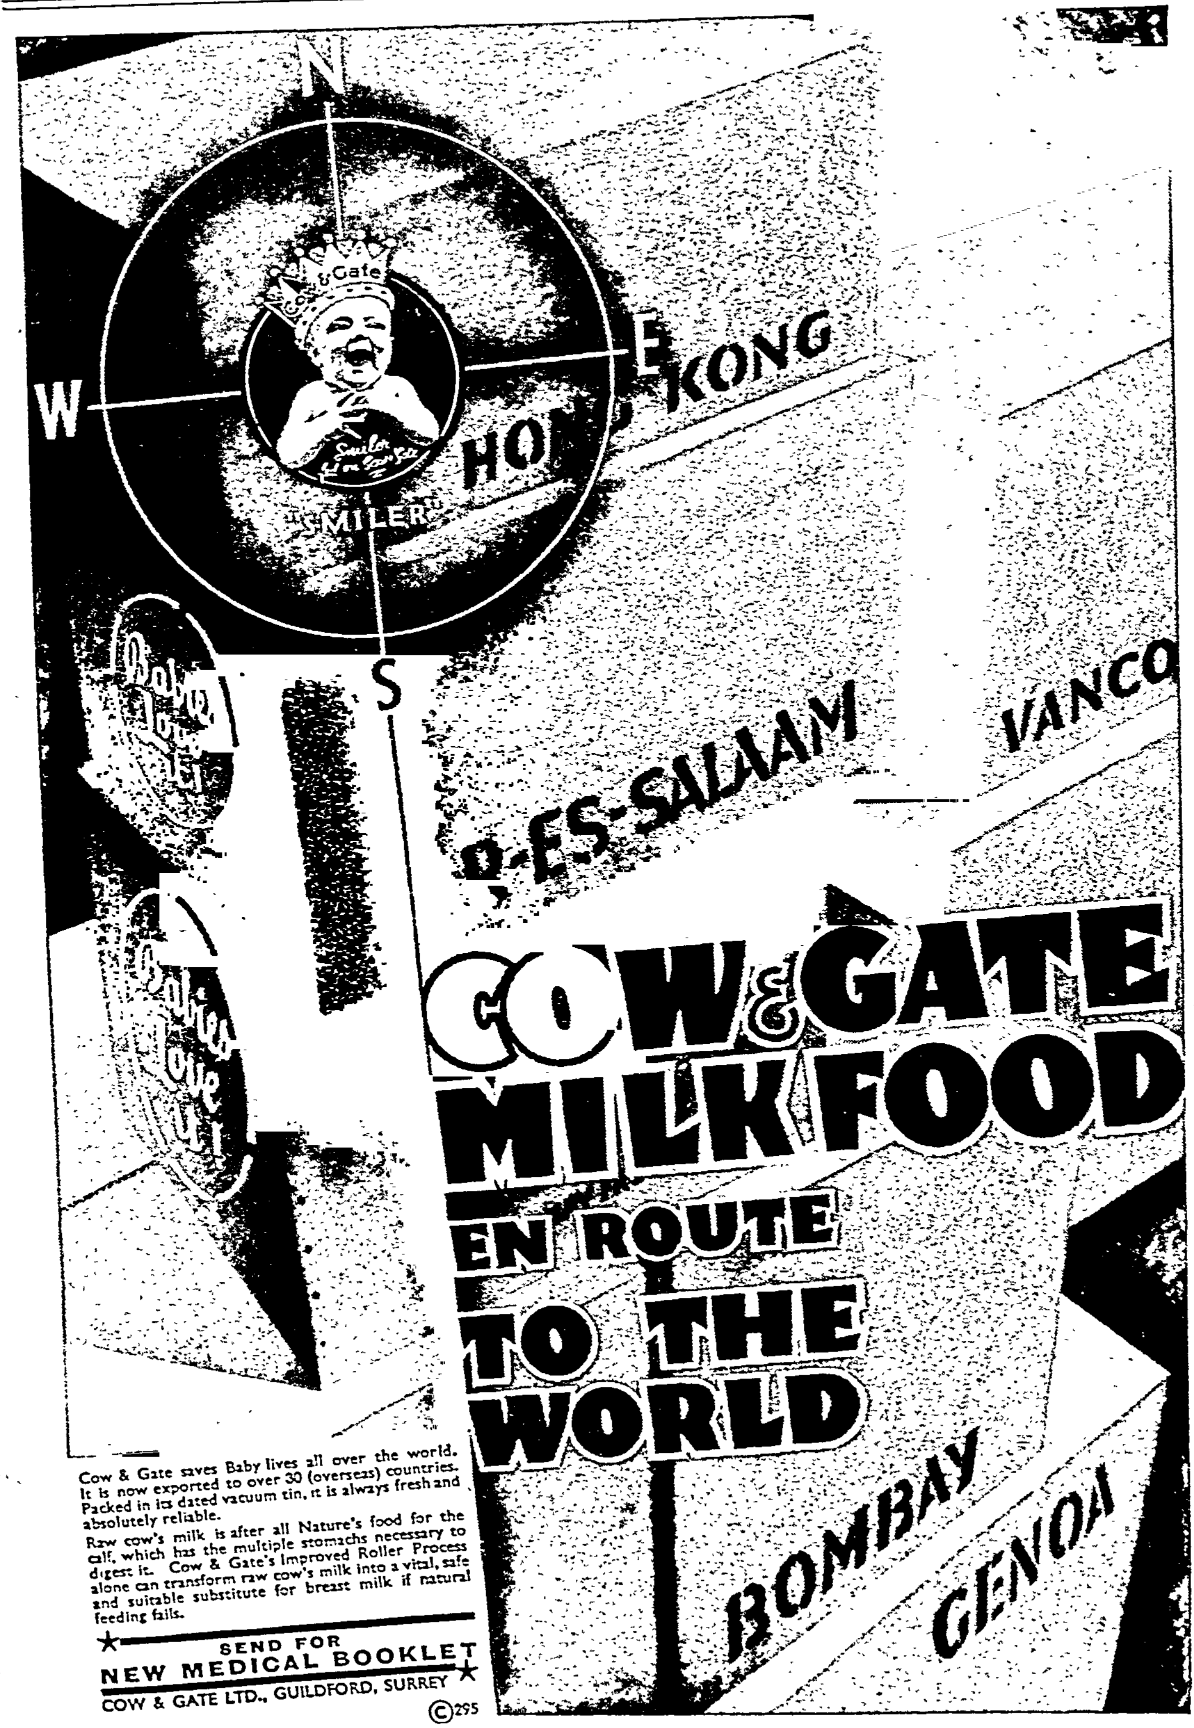
IN this third edition Mr. Aleck Bourne has enlisted the coöperation of Mr. Leslie Williams. Drastic revision and the introduction of new material have greatly altered and improved the text. In its present form the book is a work of great merit which deserves and will doubtless gain international recognition. The most attractive feature is the introduction of summaries of recent contributions to the literature and the authors have judged wisely in selecting which contributions to emphasise. As they point out in the preface, they have adopted an expectant policy towards some new work, choosing to await confirmatory evidence rather than to introduce material which may prove ephemeral. The chapter on carcinoma of the cervix will prove particularly useful, for it contains a careful account of modern radiological methods and gives a reasoned opinion on the relative merits of radiological and operative treatment. Puerperal sepsis is dealt with in great detail from all points of view, and the authors show caution in attributing results to any particular treatment. The new methods of analgesia in labour are described, and the practitioner will find an admirable summary of the available methods with their faults and merits clearly recorded. Perhaps insufficient emphasis is placed upon the gas and oxygen method; it is true that the technique demands an expert anæsthetist but if one is available the method is at least as good as any. The articles on the anterior pituitary hormones and on œstrin are up to date, but are not very critical. Due regard has been paid to Zuckerman's admirable work. There is some carelessness in the proof reading, for some names are wrongly spelled—e.g., Hitchmann, Wisener, Zuchermann. The recent views on functional uterine hæmorrhage are ably reviewed and will be welcomed particularly by students, for as yet there has been no authoritative opinion on the new work. Recent criticisms of J. A. Sampson's theory of endometriosis are noted; the theory of the lutea origin is wrongly attributed to E. S. J. King instead of to Wilfred Shaw. There is no reference to recent work on leucorrhœa; the text-book theories about this condition have been upset during the last few years by German and American contributions which should be noted in the next edition. A superbly illustrated article on X rays contributed by Dr. Courtenay Gage completes the presentation.

The authors must be congratulated; the new edition should receive the attention of practitioners, but above all it will be most welcome to senior students.

Le mycosis fungoïde

By S. LAPIÈRE, M.D., University of Liége. Paris: Masson et Cie. 1932. Pp. 122. Fr.30.

THIS is a group of cutaneous maladies in which conceptions and conclusions have long lacked order and coördination, inasmuch as the term mycosis fungoides includes "a series of affections of the reticulo-endothelial tissue." These can be divided and studied in two main categories—an inflammatory granulomatous stage, in which fever, pruritus, rheumatic concomitants, &c., are sometimes prominent, and a tumour stage, in which neoplastic changes in the dermis eventually determine generalisation and a fatal issue. *Histologically this differentiation is* similarly defined. The motley collection of cells which make up the characteristic infiltrations, on which the clinical diagnosis of the granulomatous stage is based, are normal in appearance and originate from the blood. In the tumour stage the cells have taken on a malignant appearance, and tend to group themselves in strands or tubes around which, and the vessels supplying them, are noted the usual cell reactions of cancerous invasion. The two stages are due to disease of the same tissue but with entirely different reactions, the one acute and inflammatory, the other of indolent and typically malignant type. It must be realised however



Cow & Gate saves Baby lives all over the world. It is now exported to over 30 (overseas) countries. Packed in its dated vacuum tin, it is always fresh and absolutely reliable.

Raw cow's milk is after all Nature's food for the calf, which has the multiple stomachs necessary to digest it. Cow & Gate's Improved Roller Process alone can transform raw cow's milk into a vital, safe and suitable substitute for breast milk if natural feeding fails.

manner and praiseworthy efforts are made to offer scientific explanations wherever possible for the various phenomena observed in cooking; it is a judicious blend of theory and practice and can be recommended as offering quite interesting reading.

Puerperal Infection

By JAMES ROBERT GOODALL, O.B.E., M.D., D.Sc., Clinical Professor of Gynæcology and Obstetrics, McGill University, Montreal. Toronto: Murray Printing Co. 1932. Pp. 189.

THIS monograph contains the substance of the lectures on puerperal infection given by the author to the final-year students of the McGill University. The arrangement of material is different from what is customary at the present day, for there is little theoretical discussion and the subject matter is presented concisely and dogmatically. The style is that of the Victorians and shows a well-marked similarity to Matthews Duncan's "Clinical Lectures." A contribution of this kind written by a teacher of experience and ability merits great attention; it should be brought to the notice of all final-year students, for they will find the problems of puerperal infection simply presented to them through the personal experiences of a writer, many of whose opinions differ from those held in this country. The monograph compares favourably with any contribution to this subject in the English tongue.

1. Evolution of Sex and Intersexual Conditions

By Dr. GREGORIO MARAÑON, Professor at the University of Madrid. Translated from the Spanish by WARRE B. WELLS. London: George Allen and Unwin, Ltd. 1932. Pp. 344. 15*s.*

2. The Sexual Side of Marriage

By M. J. EXNER, M.D., Consultant and formerly Director of Division of Educational Measures, American Social Hygiene Association. Same publishers. 1932. Pp. 252. 6*s.*

3. Is It a Boy?

By Dr. F. ÖKLAND, Assistant Professor, Aas, Norway. Same publishers. 1932. Pp. 92. 3*s.* 6*d.*

1. The title of this book indicates Prof. Marañon's thesis that sex is not an individual attribute which possesses an immutable value. It is comparable rather to age in that it evolves in successive phases to its full development, its progress being interrupted by various crises. He holds the view, by no means unique, that the sex of every individual, even the normal, is a double one and that intersexuality to some degree or other is always present even in adult years. At one end of the scale stands the obviously pathological hermaphrodite, the possessor of an ovo-testis; at the other, the more or less normal individual with an intersexual tendency, capable of being fashioned by the moulding action of environment into either the homosexual or the heterosexual. At first sight it would seem that this belief that homosexuality is always determined by an innate predisposition to homosexual practices is a pessimistic one and a discouragement to all forms of psychological treatment, but that the author does not hold this view is shown by the emphasis he lays on early training and environment. These factors, according to him, have a decisive influence on the appearance or the inhibition of the tendency. Even when a child is born with a strong constitutional substratum of intersexuality, this may never be revealed throughout the course of a long life, or may only manifest itself when the determining causes of environment operate too strongly against normal development. Prof. Marañon has interested himself in problems of sex for a great many years. He writes not only as a Spanish academician and a professor of endocrinology at the University of Madrid, but as a clinician who has been called upon to handle the personal problems of countless patients suffering from sexual troubles. His book therefore will be equally interesting to those who approach sex from the standpoint of pure science and to those who are called upon to deal with difficulties in the consulting room. The translation has been excellently carried out.

2. Dr. Exner's book is addressed primarily to men and women approaching marriageable age and to those in marriage who have difficulties in achieving happy adjustment. From a host of mediocre books written with this object, it stands out by reason of its directness, sobriety, objectivity, and literary merits. Though the author apparently enjoys a considerable professional experience of the marital difficulties of patients, he quotes freely—perhaps too freely—from the statistical material of other authors. The data of Drs. K. B. Davis, R. L. Dickinson, and G. V. Hamilton are frequently referred to in such a way as to throw their essential findings into clearer relief than they enjoy in the original volumes, which are so heavily burdened with statistics and tables as to make it difficult to see the wood for the trees. Extensive appropriate quotations are also made from the works of Frederick Harris, Knight Dunlap, Havelock Ellis, Lichtenberger, and others. The book has seven chapters. The first, entitled Sex Life, serves as an introduction to the second and third, which describe respectively the reproductive systems of the two sexes, illustrated by five excellent drawings by Dr. Dickinson, and the differences between male and female sexuality, which are treated in accordance with Dunlap's exposition. Then follow the important chapters—two upon the factors contributing to sexual maladjustment, and a third on the elements which go to make up an ideal marriage. The only shortcoming of the volume is the almost complete absence of original subject matter or treatment; it might have been written by a lay author with no first-hand experience, who had carefully digested the literature of his subject. This, however, is not a serious defect; the book is written with tact and delicacy, and it can be safely recommended by the medical man to the persons for whom it is written.

3. The flippant title of Dr. Ökland's little book belies its essentially serious aim. The question of sex determination is one in which every prospective parent is interested, and the medical practitioner is not infrequently asked what contributions modern science has made to its solution. To lay persons posing this conundrum this book can be safely recommended. In the compass of its 20 short chapters, some of them illustrated by good diagrams, is compressed a readable and instructive summary of existing knowledge on this subject. The essentials of the chromosome theory are simply explained and an indication is given of the directions in which we may look for a future solution of the problem of human sex determination. In view of the large number of misleading works that have appeared on this subject Dr. Ökland's book is welcome.

THE LANCET

LONDON: SATURDAY, SEPTEMBER 17, 1932

THE NATION'S BILL FOR HEALTH

When the family budget is hard to balance, the wise man inquires carefully into his expenditure, asking what he is getting for his money, whether it is worth having, and whether it can be obtained for a smaller price. The nation's doctor, Sir George Newman, remembers this in presenting his annual report on the state of the public health.[1] He asks, first, what are the results of the public health services, and, secondly, what are these results costing. His definition of what we are getting for our money is survival, health, and capacity. He instances the extermination of leprosy, plague, and cholera, the lower death- and infant mortality-rates, and the increase in the expectation of life by 15 years in two generations, and declares with justifiable satisfaction that the English people do not behave like a sickly or invalid people. The apparent increase of sickness among the insured population is, he points out, an increase of claim for benefit rather than an actual increase in disease, and the contention that there is no substantial saving of life at mature ages receives short shrift at his hands. In the establishment by the State of the poor-law medical services in 1838 and the public health service some ten years later, he traces the seeds of an expanding organisation which has permeated the nation and created a "national minimum" of health requirement. The one outstanding thing that the nation is not getting is an adequate improvement in the maternal mortality figures, and the investigations made and the measures recommended to deal with this blot on our national health are obviously receiving serious attention.

The surveys of the public health service which have come down from the days of Chadwick constitute a useful form of stocktaking and of ascertaining whether or not the best possible value is being obtained for money. Those made since the Local Government Act, 1929, are of particular interest in view of the changes then introduced. The medical aspects of the old poor-law are being rapidly absorbed into the public health service within the ambit of larger and more effective units of government; the poor-law institutions have been emancipated into the service of the people as a whole; and a standard of performance has been introduced whereby county and county borough councils can measure the effect of their health activities. Sir George Newman emphasises the importance of studying not only the form of the activities of a local authority, but also their function, to ascertain in what measure they secure the separation of the treatment of the sick poor from the poor-law administration, their effectiveness in a therapeutic and preventive sense, and their coördination and economic working. He stresses the importance of effective coördination of all health services in an area, and observes that in some places this essential benefit has not been achieved. Many authorities have to cope with the adaptation of out-of-date buildings to accommodate the sick as well as the chronically infirm. In some areas it may be wise to close wards altogether and to transfer inmates to well-equipped centres, where this can meet their needs, including that of accessibility to friends. Early and accurate diagnosis is as important an economic factor as prompt and adequate treatment; both may hasten the passage of the acute sick through the institution and free the beds. The need for economy should act as an incentive to close scrutiny to make sure that the fullest use is being made of existing resources. Sometimes, for example, hospital beds can be conserved by establishing an out-patient department; in other conditions better results can be obtained only if more time and more specialised skill is made available for each patient. Some local authorities are considering the desirability of a domiciliary medical service. Every medical officer of health should estimate the hospital needs of his area on a basis of local conditions and not of "hospital beds per thousand." Sir George Newman expresses himself as thoroughly satisfied with the efficiency of the tuberculosis service, remarking only on a tendency in some areas to take too narrow a view of the service, accentuating treatment at the expense of prevention, and coördination with other departments. The selection of cases for sanatorium, hospital, or observation beds is not always beyond criticism. Corresponding defects in the venereal diseases service have been revealed; there is need for more education of the public and for fuller coördination with other health activities, and facilities for bacteriological diagnosis and tests for cure are not always adequately used. Coördination with the general practitioner is on the whole good in this service. Another economic measure advocated in this report is coöperation between voluntary and municipal services. This is regarded by the Ministry as one of the most important functions of local authorities at the present time, though admittedly not an easy one to discharge.

Our national "doctor's bill" for 1931 was £57,370,000. Hospitals and sanatoriums for tuberculosis and infectious and venereal diseases took 7 million of this; another million went in salaries; nearly 2 million for maternity and child welfare: over a million for mental deficiency; nearly 4 million for school medical services; and 9 million for the poor-law medical service. Over 30 million was spent on housing, water, sewage, and refuse. The aim of Sir George Newman and those who work with him is obviously to give such good value for this expenditure that the nation will pay its annual cheque as cheerfully as the average citizen pays the account due to his family doctor.

RHEUMATOID AND OSTEO-ARTHRITIS

Amidst the recognised difficulties in treatment of advanced cases of Rheumatoid and Osteo-Arthritis it is not generally realised that many patients have been restored to active life after being bedridden and suffering great pain for years.

For the description of cases see "Ambulatory Treatment of Fractures and Diseased Joints by the Hoefftcke Splint," *The Medical Press and Circular,* April 27th, 1932, pages 348–351.

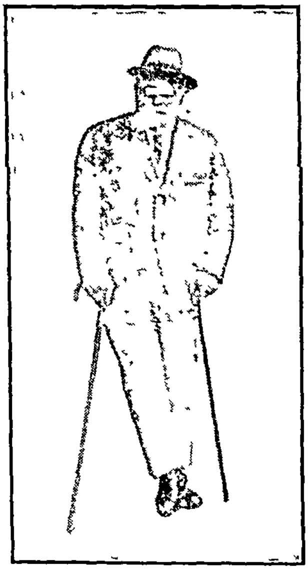

FIG. 1. July, 1929
Mr. S. Hip-joint adducted.

Mr. S., aged 67 years, was sent to me by Dr. M. with a very painful osteo-arthritic hip. The limb was adducted, with an apparent shortening of about 2½ inches. The hip was manipulated on my special extension table, July, 1929, and free movement with good abduction was obtained. Three months after my extension splint was first applied, in August, 1929, Mr. S. was enabled to go fishing and shooting without pain in the joint. Two years after the extension splint was applied it was removed, with free and painless movement as the result. Doctors in attendance and patient well satisfied with the movement and improvement in shape of the joint surface as shown in Figs. 1, 2, 3, 4.

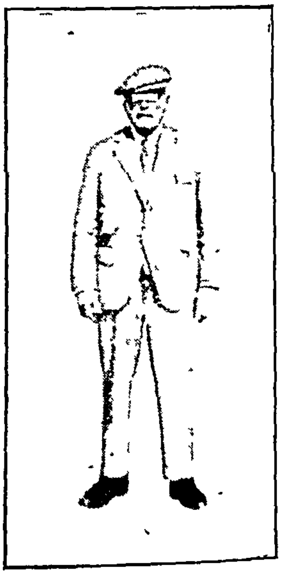

FIG. 2. February, 1931.
Mr. S. Hip-joint abducted.

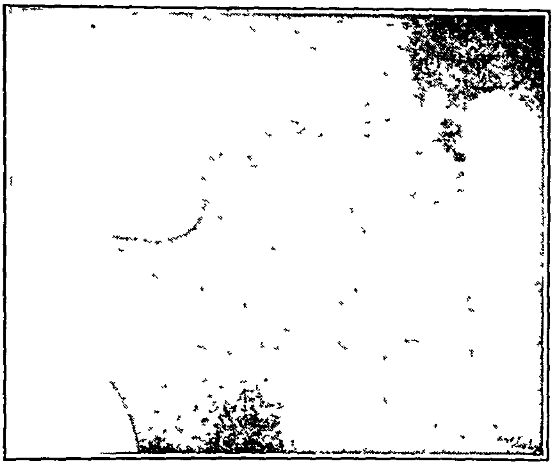

FIG. 3. July, 1929
Shows the hip-joint practically ankylosed in the adducted position with osteophyte showing one upper view of acetabulum. Patient hardly able to walk and in great pain.

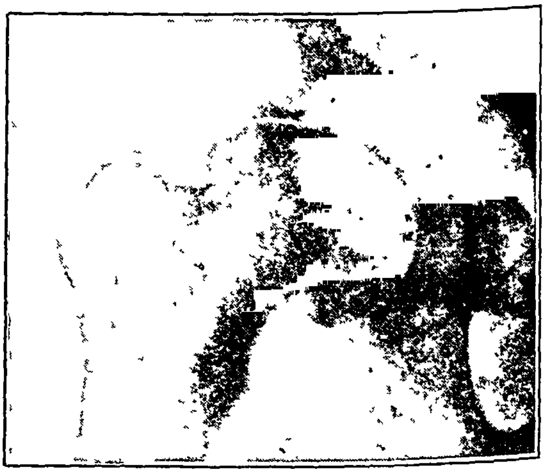

FIG 4. February, 1931.
Shows spike absorbed; cavity filled in, head of femur covered with new cartilage resulting in free abduction with full painless movement in the joint.

Particulars and illustrations of this treatment will be forwarded on application, and original radiograms of these and other cases can be shown by—

CAREL A. HOEFFTCKE, 7, HARLEY STREET, LONDON, W.1

NO CASE TREATED WITHOUT MEDICAL SUPERVISION.

moderate uncomplicated; (2) fulminating toxic; (3) anuric; and (4) continued and ermittent. He has a word to say on the effect of *ovement on the prognosis*. It is the general inion that the percentage of relapses is greater the cases that have been moved, but in his view larger series of cases is necessary before this is cepted as true. The point is important, not ly from the point of view of treatment, but also view of BLACKLOCK and MACDONALD's claim at muscular movement is dangerous because it oduces an excess of sarcolactic acid. Dr. ROSS tes the case of a prospector who, whilst cycling journey of 20 miles, developed blackwater fever. e completed this journey and also one by rail of 0 miles to Salisbury before reporting sick and et made an uneventful recovery. That no treatent as yet devised has especial claim to attention obvious from the depressing fact that the deathate is fairly uniform in the various parts of the orld where the disease is encountered despite the ariations in the treatment employed. Dr. ROSS ppears to favour intravenous alkaline injections nd blood transfusion, but notes that though large number of authors have published their ethods the total number of cases covered by all eports is small. If his verdict here, as elsewhere, s mainly negative, it is because he has brought a ritical spirit to his task and has cleared the ground y showing how little real evidence exists for or gainst many of the theories on blackwater fever that have been propounded.

HEALTH IN ENGLISH PRISONS

APPEARING (like many other official documents) without undue haste, the recently published annual report[1] of the Prison Commissioners deals with the year 1930. As usual it contains ample proof of the admirable health of our prison population, thanks to the simple and regular life, the plain and wholesome food, and the careful medical supervision, which is the more effective because prisoners are prompt to complain of any illness, and thus the doctor has a chance by early treatment to prevent serious developments. The medical officer of Hull prison remarks upon the rapidity with which men lose their coughs who on reception were noted as suffering from chronic bronchitis; the prison rules prohibit tobacco and thus remove one cause of irritation. The records of specific diseases include one case of small-pox: the patient had been many months in custody, no previous case was known at the prison, and the origin was untraced. Contacts were isolated unless voluntarily vaccinated, and no other case occurred. Detailed notes are given of an unusual outbreak affecting five members of the female staff of a prison, associated with the sickness and death of a recently imported green Amazon parrot. In each case there had been direct contact with the parrot, whose symptoms indicated disease communicable to human beings; no other cases occurred.

As in previous years, attention is drawn to the mistaken policy of certain courts of summary jurisdiction, where the bench sentence a prisoner to a term of imprisonment and ask that he may be kept under observation during the currency of the sentence so that the bench may be informed of his mental condition at the expiration. Magistrates should follow the practice of assizes and quarter sessions and call for medical evidence before proceeding to dispose of the case. A man's mental condition may be as relevant to the charge as any other item of evidence. Moreover, as Dr. NORWOOD EAST observes in the chapter containing the report of the Medical Commissioner, conviction and imprisonment may introduce elements which obscure the mental reactions associated with the offence. It is important that magistrates should also realise that, since the Mental Treatment Act of 1930 has encouraged the setting up of outpatient clinics for the treatment of mental disease, and has sanctioned the reception of voluntary patients in mental institutions without certification, the submission to treatment may well be made a condition in a probation order. If mental treatment is to be beneficial, it must be applied early. "If adequate provision is made generally for the mental treatment of in- and out-patients, there is reason to hope that a certain number of criminal careers may be checked." Certainly the probation officer, who too often has no experienced medical practitioner to advise him, may hope to be spared anxiety over troublesome cases of minor abnormality and temperamental instability if the facilities offered by the Mental Treatment Act are sensibly accepted. Dr. EAST points out the special advantage of voluntary treatment in a mental hospital for cases of attempted suicide. The number of persons sentenced to imprisonment for this offence is now very small. The police take proceedings only when the accused requires detention in his own interests. The community does not desire severity of sentence and an important body of medical opinion considers imprisonment illogical for persons who attempt to take their own lives. The great benefit derived by these cases from treatment at present received in prison hospitals is evidence of the value of advantages now made possible by the Act of 1930.

Dr. EAST concludes with some sensible comments on the conduct of psychiatric investigations on law-breakers. It is important, he says, to avoid any indication that undue emphasis is attached to abnormal conduct, thus suggesting morbidity to the criminally inclined and encouraging mental invalidism. "Society and the criminal are better served if the latter can be made to cultivate a sense of social responsibility."

MENTAL TREATMENT ACT, 1930.—The Board of Control has issued a list, revised up to August, 1932, of some 2800 medical practitioners who have been approved by the Board for the purpose of making recommendations under Section 1 (3) and Section 5 (3) of the Mental Treatment Act, 1930. The names are first given in alphabetical order, with qualifications and full postal address, followed by a local list of cities and towns where approved practitioners reside. Copies of the list can be obtained on application to the Board of Control at Caxton House West, Tothill-street, London, S.W.1.

[1] H.M. Stationery Office. Cmd. 4151. 1s. 6d.

Those who examine this report in detail may not agree that all the items represent equally valuable service, but will recognise that the nation is well served by its public health organisation, and that it is being administered with keen discrimination.

◆

BLACKWATER FEVER

SYSTEMATIC work on blackwater fever in Southern Rhodesia was first started in 1922–23 when J. GORDON THOMSON investigated the parasitology of subtertian malaria with especial regard to the part it plays in the production of this disease. H. S. LEESON then attacked the problem from the entomological side, and now Dr. G. R. Ross presents the results of an exhaustive survey[1] extending over four strenuous years. The work was rendered intricate and arduous by virtue of the conditions under which it had to be undertaken. Amongst the rural population to which the disease is mostly confined in Southern Rhodesia the cases are comparatively few and widely scattered, so that it becomes almost impossible to secure adequate material for biochemical studies in the early stages of the cataclysm when alone information of vital importance can be secured. Certain important facts have, however, been elucidated. In the first place, as far as Southern Rhodesia is concerned, the relationship between malaria and blackwater fever may be regarded as established; it is a manifestation of infection with malignant tertian malaria. It is true that certain similar features in the epidemiology of the two diseases might be explained by the theory of a common vector. Thus the transmission of both the malaria parasite and a hypothetical blackwater fever virus by *A. gambiæ* and *A. funestus* would explain the absence of both diseases from districts from which these mosquitoes were absent, but it would not explain the infrequency of blackwater fever in the first year of residence or its development long after removal from an endemic region, nor would it explain the immunity of the native inhabitant or the frequency with which attacks of malaria precede the outbreak of blackwater. How far infection with varieties of the malaria parasite, other than malignant tertian, can predispose to the development of blackwater fever cannot be determined, at any rate, in Rhodesia. That quinine is an excitant in the production of blackwater is a popular belief firmly held in Rhodesia, and Dr. Ross is not able to disprove it. In some of the cases cited in the text the connexion seems almost impossible to escape, but considerably more evidence will have to be accumulated before any causal relation between quinine and blackwater fever can be established on a satisfactory statistical basis.

The greater incidence of blackwater fever in males is attributed to the circumstance that men engage much more freely in occupations which bring them into contact with the primitive and undeveloped conditions which appear to favou its onset. In Rhodesian-born Europeans th disease is rare until the age when they star *travelling* to sparsely populated areas. Anothe interesting fact in the epidemiology is that th curve of increase and decline follows with regularit the curve of the rainfall after an interval of thre months. Though susceptibility to blackwater feve may be increased by previous attacks, there i no indication that the disease becomes mor dangerous with each attack, indeed, in Rhodesi the mortality-rate from blackwater fever wa found by Dr. Ross to be greatest in the firs attacks. One man under his observation ha four attacks during a period of about 12 year each lasting two to three days with no untowar complication, recovery being complete. H eventually succumbed to his sixth attack, followin suppression of urine. Dr. Ross is in agreemen with previous observers in finding no justificatio for the suspicion that certain houses predispos to infection. In his view susceptibility is i inverse ratio to the extent to which the individu has been protected against malaria. He does n consider increased fragility of the erythrocyt to be a factor of ætiological importance. T mechanism of methæmoglobinæmia interests hi and he cannot accept the view of BAKER and DOD that this results from the pH value of the urin He has studied the chemistry of the blood i malignant tertian malaria as well as in ful developed hæmoglobinuria. As regards bloo sugar content no significant results were obtainabl but abnormalities in the non-protein nitrogeno constituents, especially blood-urea, supply eviden of a defect in the concentrating ability of t kidney in the early stages of the disease. Ho far this defect is dependent upon the toxic actio of hæmoglobin and how far on the disturban of function consequent upon the blocking of t renal tubules by precipitated hæmoglobin difficult to say. The indirect van den Berg reaction obtainable in malaria and blackwat fever is an indication that bilirubinæmia in bo diseases is a direct result of intravascular hæmolysi A possible explanation of hæmoglobinuria is th a renal threshold value exists for hæmoglob and that when the amount of hæmoglobin in t plasma exceeds its value the pigment appears the urine. Dr. Ross gives reasons for rejecting t ingenious sarcolactic acid hypothesis of BLACKLO and MACDONALD (1928); nor, after a searchi biochemical investigation of the urine, can confirm the theory that acidosis is a factor eith precipitating hæmolysis, or even favouring t action of some other agent.

On the clinical side Dr. Ross has not been ab to find any recognisable pre-blackwater phenomen The cases under his personal observation all aro during the attack of malignant malaria and the was nothing in the general condition of the patie or in the biochemical or serological manifestatio to demarcate such cases from others. He recognis a classification into four clinical types: (1) mi which has since been fatal to many defendants who might have escaped under the rule of compulsory silence. Be that as it may, Laurie was found guilty, though only by the bare majority of eight jurymen to seven. His trial, begun on a Friday, had been compressed into two days to avoid its lasting over the week-end, the judge not completing his summing-up till nearly 10 o'clock on the Saturday night. A petition for his reprieve represented inter alia that the evidence had been entirely circumstantial, and that there was a mere balance of medical opinion; it hinted also at insanity, a plea not mentioned at the trial. The recent sentence of death on Mrs. Maybrick at Liverpool Assizes had just been commuted, and many thought that Laurie too should have the benefit of the doubt. The Scottish Office referred the question of Laurie's mental condition to three alienists who reported him of unsound mind. His sentence was consequently commuted to penal servitude for life. In 1910 he was transferred from the convict prison at Peterhead to the criminal lunatic department of Perth prison, being officially certified as suffering from progressive dementia. In 1930 he died of paralysis.

---

[1] Researches on Blackwater Fever in Southern Rhodesia. By G. R. Ross, M.B., Ch.B., Ph.D., D.P.H., Rhodesian Research Fellow, London School of Hygiene and Tropical Medicine. No. 6 of the Memoir Series of the London School of Hygiene and Tropical Medicine. London: Published for the London School of Hygiene and Tropical Medicine by John Bale, Sons and Danielsson, Ltd. 1932. Pp. 262. 10s. 6d.

The plea of insanity is not a favourite one with defending counsel in criminal trials. It prejudices their vigorous controversion of facts alleged by the prosecution. Instead of whole-heartedly protesting his client's innocence, the advocate has to say, "No one but a madman could have done these acts." Moreover, the advocate knows that a successful plea of insanity may condemn the accused to a life-time of imprisonment in a criminal lunatic asylum. Though the alienists' report upon Laurie's mental condition was never published, their apparently unanimous finding that he was of unsound mind (not necessarily, of course, criminally irresponsible) saved him from the gallows but doomed him to die in prison after 40 years' detention. Students of folklore may be interested in one curious fact. Many of Rose's belongings were produced at the trial but his boots had disappeared. The defending counsel asked questions about the condition of the soles (relevant to the theory of a slip on the rocks); the police could describe the condition of the boots but could not actually produce them. It turned out that the serjeant had told the constable to put them away, and that they were buried on the shore, deep under the pebbles below high water mark. Mr. Roughead says he is credibly informed that this somewhat irregular disposal of the boots was due to the Highland belief that the dead man's ghost would thereby be prevented from "walking" to the disturbance of the living.

DEHYDRATION IN ECLAMPSIA

THE possibility has recently been entertained in several quarters that eclampsia and the pre-eclamptic state are due to excessive secretion of the pressor-antidiuretic hormone of the pituitary. Injection of pituitrin does, of course, cause an increase in blood pressure and a diminished excretion of water, signs which are characteristic of the "pregnancy kidney." The supporters of this conception believe that the necrosis of the liver and the renal changes are due to ischæmia, and the fact that œdema often precedes albuminuria is certainly consistent with the suggestion. The convulsions of eclampsia have also been compared to those which accompany water intoxication induced by administration of water and pituitrin. Analogies of this kind, however, are not enough to raise the hypothesis above the level of mere speculation. Anselmino and Hoffman [1] have brought forward more direct evidence. They claim to have demonstrated that ultrafiltrates of eclamptic blood exert an antidiuretic effect when injected into rabbits. This is an extremely important observation, but the rabbit is a treacherous experimental animal, and further confirmation is desirable. Profs. J. O. Arnold and Temple Fay, however, have accepted the view that the toxæmias in question are essentially manifestations of water intoxication, and in a recent paper [2] they urge that the present methods of treatment should be remodelled accordingly. They condemn the custom of giving large quantities of fluid with the object of flushing out hypothetical toxins and advocate instead a régime of extreme fluid limitation. This is combined with mild purgation and, when convulsions have occurred, with lumbar puncture and the exhibition of luminal. It is their practice to measure the amount of urine excreted in the first 24 hours and thereafter to limit the fluid intake to this amount or less. The normal demands of skin, lungs, bowel, and kidneys for water are considerably in excess of this intake, and the patient must consequently draw on the waters of her tissues. The authors have marred their paper by an unwieldy discussion of theoretical considerations, only some of which are relevant to their subject. It is unfortunate that their meaning is often obscure, since the bare clinical results of the methods recommended are sufficiently striking to demand the serious attention of the obstetrician. Dehydration appears to check the development of the pre-eclamptic state, and to curtail the convulsions in established eclampsia, and is certainly worthy of more extended clinical trial.

INDUSTRIAL HEALTH

THE twelfth annual report of the Industrial Health Research Board [3] covers the work of the Board up to June 30th. It contains a valuable review of the investigations carried out since the Board was born some 13 years ago in relation to modern industrial conditions. To-day we appreciate that health is a first requisite for efficiency, and that health depends on successful adaptation to environmental changes. The mere headings under which this review is presented indicate the importance of physical and psychological surroundings to the modern industrial worker. Studies of atmospheric conditions have revolutionised ideas upon ventilation. They are revealing what are the best conditions of temperature, humidity, and air movement for comfort in buildings where men and women work, and show also that these conditions also make for productive activity, for reduction in the frequency of invalidity, and the incidence of accidents. Illumination and noise are two other factors about which much has been disclosed of immediate value to the economics of industrial output. On the other side, the human factor has been intensively investigated in its reactions and in methods of work, in order to conserve, and not waste, human energy. The effect of rhythm on muscular effort, the benefit arising from rest pauses, the fallacy of long working hours, the best pace to wheel a barrow, and the best way to load one, are only some of many problems successfully tackled. Still there remain for note the recognition of the influence of the personality of each worker, and of how it may be estimated and used to the common advantage of

ANNOTATIONS

CLASSIFICATION OF THE CEREBRAL GLIOMAS

Of discussions at the International Neurological Congress at Berne last autumn one of the most important was on the pathology of brain tumours, especially of the gliomas. This is the subject of two papers, by Percival Bailey and by G. Roussy and C. Oberling, in the June number of the *Archives of Neurology and Psychiatry*, which also contains a valuable review, by F. C. Grant, of the diagnosis and treatment of intracranial growths in general. The earlier classifications of gliomas suggested by Roussy and his collaborators in 1924, and by Bailey and Harvey Cushing in 1926, appeared to have little in common, and Roussy criticised Bailey's classification somewhat forcibly when it appeared. But in their later work these workers appear to have reached a large measure of agreement, and the gap which once separated them would scarcely be guessed by anyone who reads the papers now published. This is a result partly of fuller understanding by each of the other's meaning, and partly of acceptance by the French authors of several of the types suggested by Bailey. For some of these there is still a difference of nomenclature, implying a difference of view as to the nature of the tumour. Thus Bailey's medulloblastoma is called by Roussy and Oberling neurospongioma. This name, which was first suggested by Hoerner, emphasises the pluripotential character of the cells from which the tumours arise and the close relationship which many of them possess to the neuroblastomas. The oligodendrogliomas and ependymomas are accepted by the French authors, who also separate Bailey's polar spongioblastoma from other forms, but are inclined to group it with the oligodendrogliomas rather than with the tumours arising from undifferentiated astrocytes. The chief point which remains at issue is the subdivision of the astrocyte group which Bailey still separates into three different types, astrocytoma fibrillare, astrocytoma protoplasmaticum, and astroblastoma. For Roussy and Oberling these are variants of one type, for the appearances to which the names protoplasmic astrocytoma and astroblastoma have been given appear to them to result from degenerative and reactionary changes in the neoplastic astrocytes, rather than from an alteration of tumour type. In this they are supported by W. Penfield, who does not recognise the existence of the type astrocytoma protoplasmaticum, and by the appearance of astroblast-like cells in the encephalitic lesions produced by radium. It seems likely that later work will justify this point of view.

No less interesting is Bailey's confession that he regards most tumours of the glioma group as anaplastic, arising rather from adult cells by dedifferentiation than from cell-rests of incompletely differentiated cells. The nomenclature of the various forms in his classification, being based on the stages of differentiation of the astrocyte, gave the impression that he accepted the Cohnheim cell-rest hypothesis as applicable to most gliomas; and this impression was not fully corrected by his discussion on their ætiology. Roussy's most cogent criticism of the original classification was directed to this point. Now, however, this difference of opinion seems to have vanished. Both workers accept a developmental origin for certain types, such as the medullo- and neuro-epitheliomas and the medulloblastomas, and both regard the common glioblastomas and astrocytomas as anaplastic.

After some years of discussion and doubt we seem, therefore, to be near a classification of tumours of the glioma group which has international sanction. The value of this classification is emphasised in Bailey's paper, in which he stresses the importance to the surgeon of knowing what type of tumour he is dealing with—before, during, and after the operation. The six years that have elapsed since the publication of Bailey and Cushing's monograph have proved this to be largely true; but they have also shown that gliomas of the same type may vary greatly in their malignancy and rate of growth, so that metastases along the walls of the ventricles or down the spinal canal may occur in such slowly growing types as fibrous astrocytomas and oligodendrogliomas. These facts, instead of being deterrent, should stimulate us to further study of gliomatous tumours directed especially to the evidences of malignancy and the methods of spread. The papers under review provide a classification on which such research may well be based.

THE ARRAN MURDER

In the laboratory of the Department of Forensic Medicine in the University of Edinburgh there is preserved the jawbone of Edwin Rose, an Englishman who was found dead on Goat Fell in the Isle of Arran in 1889. Thereby hangs the tale of the trial of John Laurie for murder, retold in the "Notable British Trials" series with all his usual skill and enthusiasm by Mr. William Roughead,[1] who can claim to have been present at the proceedings 43 years ago. Rose made friends with Laurie on his holidays. The two climbed the mountain together, and Rose was never seen alive again. Eventually his body was found hidden under a boulder on the hillside, his head battered in, and his pockets rifled. The coat was drawn over the head, and the hiding-place had been carefully built up with stones and turf. The head injuries were terrible. The facial part of the skull was wanting; the left side of the head was smashed into fragments; the upper jaw was detached from the cheekbone. The prosecution said these injuries had been inflicted by a heavy blunt instrument, such as a large stone, the blows being struck from above downwards. It was a case of murder by a man who wanted to conceal all traces of his victim and to prevent identification. Laurie's subsequent conduct and movements were highly suspicious; he was found in possession of the dead man's clothes and other property, and he was tried on a charge of murder. Three doctors, one of whom was Littlejohn, gave their reasons for believing that the dead man's condition was not due to accident. Littlejohn, in particular, laid stress on the dislodgment of the upper jaw, and on the quite uninjured abdominal organs. On the other hand, three Edinburgh surgeons, who had not seen the body for themselves, supported the defence by attributing the injuries to a fall down the hillside. Mr. Roughead reminds us that the Criminal Evidence Act of 1898 had not been passed when Laurie was tried. Laurie was thus unable to tell his own story in the witness-box with the attendant perils of cross-examination—a risk countries had ratified, and not more than four of the non-manufacturing countries had either ratified it or acceded to it. It was contemplated that all the necessary deposits of ratification would be received by April of next year; and it would seem that some means of expediting the process will require consideration. It will be interesting to learn what report the Opium Advisory Committee has to make to the Assembly of the League on their instruction to collect information with a view to yet another conference on the limitation of the production of opium, and of the cultivation and harvesting of the coca leaf. There has also been in session a commission of pharmacological experts, appointed by the health committee, to investigate methods of standardising the morphine content in opium preparations and the cocaine content of coca leaves, whose report should prove instructive.

---

[1] Trial of John Watson Laurie (the Arran Murder). Notable British Trials Series. Edited by William Roughead. Edinburgh and London: Wm. Hodge and Co. 1932. Pp. 285. 10s. 6d.

The Egyptian police, under the vigilant administration of Russell Pasha, have achieved the detection and expulsion of the organiser of an important gang of traffickers in the Levant. This case led to the discovery of a secret heroin factory in Stamboul from which it appears that in one transaction some five tons of heroin were consigned to the Egyptian trafficker for £15,000. Russell Pasha informed the conference of 1931 that the convention which they had drafted was "not the convention of direct limitation which some of us had hoped to see," and it is clear that much remains to be done to achieve the object aimed at by the first Hague opium conference of 1911–12—viz., to limit, by international coöperation, the production and distribution of dangerous narcotics to medical and scientific purposes exclusively.

ERYTHROBLASTOSIS OF THE NEW-BORN

FRESH evidence has recently been brought forward which suggests that the clinical syndromes of congenital hydrops and icterus gravis are manifestations of the same underlying pathological condition, to which the name erythroblastosis of the new-born has been given. This pathological condition consists of a continuation of, or reversion to, the embryonic level of blood formation. Large numbers of nucleated red cells occur in the circulating blood, and active hæmopoiesis is found in the liver, spleen, pancreas, kidneys, suprarenals, thymus, pituitary, and lymph glands, as well as in the bone-marrow. S. H. Clifford and A. T. Hertig, in a recent review of the literature,[1] claim that the disease is more common than is generally believed. Within nine months they have seen seven proven cases giving an incidence of 1 in 340 births. Both clinical types react well to small and frequent blood transfusions, but the prognosis is bad unless prompt measures are adopted. These include the administration of fluids and, if anæmia persists, of small doses of iron and ammonium citrate. The question of early diagnosis is of great importance, and is as much an obstetrical as a pædiatrical problem. The mother's past history may suggest that erythroblastosis has occurred in a previous pregnancy. The vernix caseosa is of a characteristic thick golden-yellow colour, which is of great diagnostic significance. The placenta is often abnormally large. The abdomen may be prominent owing to the presence of free fluid and to enlargement of the liver and spleen. Severe anæmia and œdema may be present. Such findings should lead to an immediate examination of the blood. At birth there should not be more than five nucleated red cells seen in counting 100 white cells. On the second day there should be fewer than one nucleated red cell per 100 white cells. Clifford and Hertig state, however, that an abnormally high nucleated red cell count is not pathognomonic of erythroblastosis of the new-born unless associated with other signs. The relationship of the condition to idiopathic anæmia of the new-born remains to be determined.

TOXÆMIA AND CARBOHYDRATE METABOLISM

THE clinical observation that the diabetic state is aggravated by infection is borne out by the more recent discovery that carbohydrate metabolism in the normal animal may also be impaired by the same cause. The impairment has been variously ascribed to suppression of insulin secretion, to stimulation of the suprarenal and thyroid glands, and to actual destruction of insulin by the circulating toxin. But the only factor in the carbohydrate-regulating mechanism that has been investigated at all fully either in man or in animals has, however, been the blood-sugar. B. Corkill,[1] considering that the disturbance is probably more deep-seated, has now approached the problem from the point of view of deposition of liver glycogen. It has been shown by M. W. Goldblatt[2] that in normal young rabbits small doses of insulin markedly increase the deposition of glycogen in the liver. Goldblatt regarded this as a "locking" action of insulin (preventing the conversion of liver glycogen to glucose), though Corkill, in confirming his results, suggested that it is due to the action of adrenaline secreted owing to insulin hypoglycæmia. In his present study, Corkill has investigated the deposition of glycogen in the livers of young rabbits rendered toxæmic by injection of diphtheria toxin—a substance known to cause particular damage to the suprarenal bodies. He finds that the normal effects of insulin and of adrenaline alone in causing accumulation of liver glycogen are suppressed, and also that when the two hormones are given together, in proportions which cause glycogen deposition in the liver of the normal animal, the effect is again suppressed by the toxæmia. Blood-sugar estimations indicated that toxæmia made the animals resistant to the effect of insulin, in that recovery from hypoglycæmia was abnormally rapid. This rapid recovery Corkill attributes to an excess of the normal effect of adrenaline reaction in promoting recovery from insulin hypoglycæmia—a supposition supported by the fact that ergotoxine removed the abnormally early recovery. It is significant, however, that although ergotoxine abolished the insulin resistance shown by the blood-sugar, it did not facilitate the deposition of glycogen in the liver.

THE NERVOUS SYSTEM IN PERNICIOUS ANÆMIA

THE frequency of involvement of the nervous system in pernicious anæmia has seldom been studied closely. Text-books differ in their opinions, but generally would have it believed to be relatively uncommon. R. S. Ahrens,[3] however, in a routine examination of 189 cases of proved pernicious anæmia, finds in over 97 per cent. definite signs of dysfunction of the nervous system. As an index of disturbance he has taken vibratory sensation, and he holds that this offers the earliest conclusive evidence of nervous employer and employed. Some persons are more susceptible than others to boredom; others seem to prefer monotonous processes which give them freedom for daydreams; some appear to possess an innate liability to accident which, however, is usually associated with lack of skill at the process concerned and with a tendency to periods of invalidity; others, with a charmed life, go accident-free, are skilled craftsmen, and rejoice in sound health. These variations are largely reactions to environment, the adjustment of which, where possible, means not merely success in industry, but harmony in the social community. The work of the Board is thus no mean contribution to human progress.

NEURAL IMPULSE AND THE PSYCHONEUROSES

CENTURIES before neurology had enlightened us with regard to the functions of the central nervous system, philosophers and experimentalists were preoccupied with the relationship of body and mind. The effort to find a locale for the soul was solved for Descartes by placing it in the pineal body. Since that time mechanism and psychology have struggled for domination, but with every advance in experimental neurology, psychology has apparently retreated. This retreat, however, indicated rather an acceptance of neurological explanations of behaviour than a sacrifice of essential vocabulary. One of the most important problems in the relationship of the body-mind problem is brought into relief in the study of the life of feeling and emotion, particularly as these are manifest in the psychoneuroses. Where the purely intellectual or cognitive functions are concerned, psychologists have been prepared to accept the cortex of the brain as the essential substratum of mental activity; but the variability and indefinite quality of emotional disturbances have made psychologists sceptical of neurological explanations. The work of Henry Head on sensations, however, has allowed for no doubt that the thalamus is concerned with the appreciation of affective tone, and with coarse sensibility as opposed to the fine adjustment or discrimination inherent in cortical functions. Mr. G. G. Campion[1] has recently attempted to define more clearly the thalamo-cortical share in the life of feeling and emotion. The thalamus is intimately concerned with the regulating and inhibiting of autonomic activity, seeing that it is the end station for sympathetic and parasympathetic communications. In this way thalamic, autonomic, and endocrine functions are brought into relation with the cortex, which is the clearing house of all those associative mechanisms concerned with cognition. The work of Pavlov has demonstrated that the conditioning of behaviour, the specifying of simple instinctual responses according to circumstances, is the work of the cerebral cortex. Psychoneuroses are an illustration of the disturbances in the affective instinctual life, disturbances which qualify the way in which the subject interprets the external world—a cortical function. We welcome this neurological attempt to explain the adjustment of the organism to the varying circumstances of life; but does it vitiate the psychological concepts of conflict and repression? Every mental discipline calls for the creation of a universe of discourse suitable to its subject matter, and it is a matter of speculation whether the defining of neural mechanisms makes the psychological world of discourse superfluous. Knowledge of the undulatory theory of light and the structure of the human visual apparatus does not make us cease to speak of "an experience of red." No neural explanation of visual experiences could blot out once and for all the language of psychology, which is after all but the language of mind as a living thing. In placing the affective life in the thalamic mechanism, we give it a local habitatio and a name, but the life of the organism resides i every cell of the body. The explanation of behaviou in neural terms defines the administrative capacit of the central nervous system, but it does no necessarily explain the whole working of the organis in its struggle to live.

X RAY EVIDENCE OF INTUSSUSCEPTION

A POSSIBLE method of establishing the diagnosi in doubtful cases of intussusception has recently bee suggested by Dr. Reginald Miller. He records[1] case of subacute intussusception, occurring in a gir aged 3, in whom the condition was demonstrate radiographically both by a barium enema and a opaque meal. The patient was taken ill wit abdominal pain and vomiting on April 10th; n blood or mucus was passed per rectum. On admissio to hospital on the 13th, she was found to have rounded tumour in the left side of the abdomen an aperient enema produced a scybalous result showin traces of blood and mucus, and immediately afte wards no tumour could be felt. The child's conditio was good for the next three days, apart from irregul attacks of colic in the region of the tumour, whi had reappeared; the bowels were opened by enem On April 16th an opaque enema was given, and radiogram taken immediately after its evacuatio showed the apex of the intussusception just belo the hepatic flexure; the barium, having becon insinuated between the intussusceptum and t intussuscipiens, outlined the folds of the mucos The child remained well, and a skiagram of an opaq meal, given two days later, showed the apex of t intussusceptum at the middle of the transverse colo It was noticeable that the intussusception in t skiagrams had travelled back from the left to t right side of the patient. On April 19th no defini tumour was palpable, but a laparotomy was perform for safety's sake; it was found that complete spo taneous reduction had occurred, the ileocæcal regi still being œdematous and the adjacent glan enlarged and soft. Dr. Miller thinks that the eviden of an opaque enema might be of considerable val in the diagnosis of doubtful and acute cases intussusception. Screening could be so quick performed that it need entail no serious waste of tin

TRAFFIC IN DANGEROUS DRUGS

THE question of further action to be taken restrict the international traffic in dangerous dru and to limit their production and distribution medical and scientific purposes will come unc review by the Council and the Assembly of t League of Nations at their September sessions. T convention of 1931, which set out to secure su limitation of production, is not yet in operatio By Article 30 it cannot come into force until ratifi or acceded to, by 25 countries, including four of t following manufacturing countries: Great Brita France, Germany, Japan, Netherlands, Switzerla Turkey, and the United States. It was stated August 1st that only one of the manufacturi

CEREBRO-SPINAL FEVER

A RECORD OF THIRTY-ONE CASES, WITH SPECIAL REFERENCE TO INTENSIVE SERUM TREATMENT

By E. Ashworth Underwood, B.Sc., M.B., D.P.H. Glasg.

DEPUTY MEDICAL OFFICER OF HEALTH, CITY OF LEEDS; LATE DEPUTY MEDICAL OFFICER OF HEALTH, COUNTY BOROUGH OF ROTHERHAM

Cerebro-spinal fever naturally varies much in its severity. Hirsch[1] showed that the mortality in an epidemic might be as low as 20 per cent. In Glasgow during 1906–08 the mortality-rate was 74·8 per cent. in 910 cases treated in hospital.[2] During the war the mortality-rate fell considerably, but in the Glasgow epidemic of 1929 it was 83·6 per cent.[3] The present outbreak in Rotherham is interesting because of the high virulence of the disease, and also because of the prevalence of Type 3 of the meningococcus. This paper deals with the cases which occurred during the calendar year 1931.*

Incidence and mortality.—Between Jan. 1st and Dec. 31st, 69 cases were notified; 60 of these were admitted to the isolation hospital, and in 37 the diagnosis of cerebro-spinal fever was confirmed. I saw many of these cases before admission, and they were under my care after admission. For all cases, including six who died before admission, the case-mortality was: males, 77·3 per cent.; females, 95·2 per cent.; both sexes, 86·0 per cent. A noteworthy feature was the frequency with which adolescents and young adults were attacked. Only 14 per cent. of the patients were under 5 years, whereas the corresponding figure for the Glasgow epidemic of 1929 was 60·5 per cent. (Peters and Gunn [3]).

CLINICAL FEATURES

All the following sections deal with 31 confirmed cases who were under my care throughout their illness. Most cases showed a very acute, and many a fulminating, type of the disease. The following is a brief summary of the chief clinical features:—

Headache occurred as an initial symptom in 30 cases, vomiting in 22. Other common initial symptoms were: stiffness of neck, 19 cases; irritability, 18; depression, 11; pain in limbs, 2; convulsions, 2 (both children). After the onset headache usually masked other symptoms. Cutaneous hyperæsthesia occurred in 15 cases (48·4 per cent.).

Nuchal rigidity occurred in every case, and was usually definite on admission. Head retraction occurred in 10 patients (32·3 per cent.)—four of whom were children and three others thin subjects. This agrees with the incidence of 30 per cent. given by Worster-Drought and Kennedy.[4] Opisthotonos was seen in three cases only (9·7 per cent.). In one of these it appeared late, with the onset of chronic internal hydrocephalus. This rather rare sign is commonly associated with meningococcal meningitis—giving the "gun-hammer position." Osler [5] mentions that orthotonos is much more common, and this series of cases confirms him. Kernig's sign was present in 27 cases (87·1 per cent.). Brudzinski's signs were much less reliable. The contralateral reflex (identical or reciprocal) occurred in five cases only, the neck sign in 16 cases. All the cases which gave a positive contralateral reflex also gave a positive neck sign. Rigidity of the limbs occurred in 14 cases. Abdominal rigidity was rare, but slight trismus was seen in one case. The tendon reflexes were variable. An apparent bilateral extensor plantar response was seen in one case. Ankle-clonus was never observed.

Facial paralysis occurred in three fatal cases (9·7 per cent.). Paralysis of one arm was seen in two cases. Other conditions were: dysarthria, 2 cases; nerve deafness, 1; aphasia, 1; dysphagia, 1; epileptic seizures, 1. Coma supervened in 21 cases (67·7 per cent.)—or in all the cases who died except five.

Ocular manifestations.—Abnormalities of the pupils are important signs. Inequality was seen in 8 cases; a sluggish reaction in 5; and contraction in 2. One fatal case exhibited paralysis of the right pupil. Strabismus was very common: it was seen in 11 cases (35·5 per cent.); in 2 it was transient. This incidence is much higher than that found by Rolleston (10·2 per cent.)[6]; or by Worster-Drought and Kennedy (19·5 per cent.).[7] In the present series only one patient with strabismus recovered; in this instance the squint was slight. One of the 11 cases quickly developed a total ophthalmoplegia. Nystagmus did not occur in a single instance. Ptosis was not infrequent; it was seen in three cases (9·7 per cent.), one of which recovered. The incidence in Rolleston's cases was 3·6 per cent.[8] Retraction of the upper eyelid occurred in two fatal cases. Photophobia was noticed in 11 cases, but it is probable, as Ballantyne [9] has shown, that this was not a true photophobia, but was due to spasm of the eyelids. Conjunctivitis—mostly mild, but in one case purulent—occurred in 8 cases (25·8 per cent.). This is much higher than Rolleston's incidence of 5·6 per cent. Other ocular findings were: amaurosis, 2 cases; iritis, 1; conjunctival hæmorrhage, 1. A sign to which attention is not usually drawn is œdema of the eyelids, which occurred in 6 cases (19·4 per cent.). In 1 case it appeared on the left side only; in 2 other cases it affected both lower eyelids only. All the patients who showed the condition died, and none of them developed a skin rash.

Urinary symptoms.—The incidence of albuminuria (6 cases, 19·4 per cent.) was higher than usual in this country. Rolleston [8] found the condition in only 5 out of 143 cases. On the other hand, Cazamian [10] found albuminuria in all of 113 cases. Hæmaturia occurred in one case; this patient had the apoplectiform type of the disease, and she later developed a rash. She was not having hexamine. Polyuria was present in 11 cases (35·5 per cent.); retention of urine in 9 (29 per cent.); and incontinence of the bladder in 10 (32·3 per cent.). Some cases who had incontinence probably had a retention overflow.

Other symptoms.—Bronchitis was fairly marked in three cases. One patient showed pericardial friction; he recovered. Late cyanosis was noticed in 15 cases (48·4 per cent.), and three cases had Cheyne-Stokes' breathing before death. No definite case of rhinitis was noticed. Throat signs were usually those of chronic conditions, but three cases showed injection of the tonsils with dryness of the fauces. The tache cérébrale was frequently seen. Vaginal discharge (from which meningococci could not be cultured) was present late in the illness of a girl of 9 years. One patient showed definite abdominal tenderness on admission. On the seventh day of illness in a boy of 10 years definite blood was found in the stools; no abnormal abdominal signs were elicited in this case. The patient died.

Rashes.—The incidence of rashes in different epidemics is very variable. During the war they were quite common—e.g., Rolleston [8] gives 59 per cent. and Worster-Drought and Kennedy [11] 53 per cent. In the present series a rash was noticed in 10 cases (32·3 per cent.). In two other cases the presence of a rash was doubtful. The rashes were mainly petechial and macular, and the sites most commonly affected were the chest, thighs, and arms. Only one patient with a definite rash recovered.

Herpes developed in seven cases (22·6 per cent.). The incidence in Rolleston's cases was 23 per cent., and in those of Worster-Drought and Kennedy 35 per cent.

In the present series the herpes usually appeared between the fourth and the eighth days of disease. It was profuse in damage. Most often the sensation is first lost over the toes, after which it gradually disappears upwards towards the trunk, the arms being but rarely affected. Coincidently with this sensory disturbance, reflex activity may or may not be altered. Alteration from the normal plantar response was observed in only 28 cases; and this is the only definite sign that the disease process has attacked the spinal cord. Ahrens expresses the opinion, however, that vibratory disturbance is sufficient evidence to inculpate the cord—a statement which may not meet with the assent of all neurologists. In only 39 cases has he been able to study the value of liver or similar therapy; and he concludes from his observations that this method of treatment has no demonstrable effect on the vibratory disturbance and cannot be credited with causing definite alteration of the reflex activity. In this respect he is in accord with D. McAlpine,[4] but in opposition to C. C. Ungley and M. M. Suzman.[5] Opinion thus remains divided about the value of liver therapy for the correction of nervous disturbance. Attention is also drawn *by Ahrens to the presence of mental symptoms in* association with anæmia: alterations which may vary from mild personality changes to a definite organised psychosis. This aspect of the disease has been the subject of investigation in the past by H. W. Woltman, who, in an extensive paper,[6] described not only the symptoms but the histological appearances in the brain. In our last issue Dr. I. Atkin recorded such a case and described the value of liver therapy in clearing the mental picture. This is certainly a part of the disease process which has received but scant attention in the past, and the benefit or otherwise of liver therapy has not as yet been assessed.

* The writer entered upon his present duties in January, 1932.

PHYSIOLOGISTS AT ROME

THE fourteenth International Congress of Physiology met this year in Rome from August 29th to Sept. 3rd. Earlier in the year there had been suggestions from some quarters that in view of the economic situation the congress should not be held. The decision of the Italian committee that it should be was justified by the very large membership. Nearly 1100 names appear in the printed lists, and the final numbers attending cannot have fallen far short of 1500. The opening meeting took place under the presidency of Prof. Bottazzi, when the members were welcomed by Signor Mussolini. The opening address was given by Prof. A. V. Hill, who took as his subject Energy Exchanges in Muscle and Nerve. His address was much appreciated by those fortunate enough to get in to the opening ceremony. A large number of members, however, excluded by the prompt closing of the doors at 9.55 A.M., were obliged to remain outside the Campidoglio until the meeting was over. Prof. Hill, caught in this crowd, was narrowly rescued in time for the meeting. Two other lectures were given during the congress: one by Prof. P. Karrer (Zurich), Über Carotinoide und Vitamin A, and the other, by Prof. Pavlov, entitled La physiologie de l'activité nerveuse supérieure. Prof. Pavlov, who was enthusiastically welcomed, showed himself to be full of vigour and vitality in spite of his 83 years. The programme of the congress contains the titles of some 450 papers and demonstrations, of which, naturally, only a small number could be attended by any individual member. Four sections ran concurrently with excellent mechanical devices in each theatre giving the number of the communications taking place at the time in the other sections. The communications in the sections were more or less grouped according to subject. This brought together those interested in a particular aspect of physiology, and gave occasion for some excellent discussions. Papers on respiration led to a discussion in which Yandell Henderson, Anrep, Douglas, Hering, Heymans, and others took part. This discussion was taken up again and carried further the next day, when a group of papers on circulation were given, led off by Heymans and Bouckaert, of carotid sinus fame. Heymans also had an excellent demonstration showing the close relationship between this structure and the respiratory centre. Other sections were devoted to a wide range of biochemical subjects, to many aspects of metabolism, to muscle and nerve, among the other numerous divisions in which physiological work must now be carried on. At this congress no member was allowed to read more *than one paper, but unless future meetings are to* be drowned in a sea of papers, it seems certain that there must be some further limitation. On the last day of the congress members were invited to the Vatican, where they were received and addressed by the Pope. After the congress an excursion was arranged to Naples, which gave members the opportunity of visiting the Aquarium and its laboratories, and of making excursions to Capri, Vesuvius, Pompeii, and Pesto. Generous hospitality was extended to members, and the arrangements for their convenience were admirable. At the final session it was reported that the committee had accepted an invitation to Russia for the 1935 congress.

Dr. Cecil Wall has been elected Master of th Society of Apothecaries.

Dr. W. Langdon Brown, consulting physician t St. Bartholomew's Hospital, has been appointe Regius professor of physic in the University o Cambridge, in succession to Sir Humphry Rolleston who retires on Sept. 30th on completion of his ter of office.

WE regret to announce the death on Monday last of Dr. Thomas Henry Craig Stevenson, who was from 1909 to 1931, superintendent of statistics a Somerset House. Dr. Stevenson's work as a medica statistician gained recognition, not only in thi country, but throughout the world. He was in hi sixty-third year.

Dr. Ian Macdonald, who died of pneumonia i London on Sept. 14th, in his 59th year, was a medica graduate both of Edinburgh and Paris, and had winter practice for many years in the Spanis province of Huelva.

NORTH MANCHESTER DISTRICT NURSES' HOME.—A maternity wing has been added to this home a Harpurhey at a cost of £11,000, and was formally opene by Lady Maureen Stanley. It is a one-storeyed buildin capable of extension; at present it contains a ten-bed ward three private wards, and an antenatal ward lighted wit vita-glass, as well as a dispensary and other offices The maternity wing is intended to be practically self supporting.

recrudescences, during which serum was also given intravenously, but he recovered after a long illness. In other cases serum was also given intracisternally, but it was evident that this route did not allow of much increase in the amount. Hence, later in the epidemic the intravenous route was adopted as an additional method, and large doses of serum were often given in this way in each case. The method had been employed by Herrick[18] during the war with encouraging results. It has been recently recommended by Banks,[19] whose experience with it is derived mainly from sporadic cases. Later in the outbreak I adopted the following procedure:—

1. Every case showing clinical evidence of cerebro-spinal fever was lumbar punctured on admission. If the fluid showed abnormal naked-eye features, and the pressure was increased, a considerable amount was withdrawn. A dose of serum was then given intravenously—usually 100 to 200 c.cm.

2. The fluid was examined for cells and organisms (microscopically). If the diagnosis was confirmed, lumbar puncture was forthwith repeated: 20 to 40 c.cm. of serum was given intrathecally. Further detailed examination of the cerebro-spinal fluid was commenced.

3. Lumbar puncture was repeated at intervals of 12 to 24 hours. Further doses of serum were given intrathecally, usually at intervals of 24 hours. After a few days the question of further intrathecal injection was determined by the amount and character of the fluid withdrawn.

4. In any event daily attempts at intravenous injection were made (100 to 200 c.cm.). Usually, and especially in children, the number of intravenous injections was strictly limited by the tendency of the veins to collapse, a feature which was very marked in this outbreak. In young children, in whom a single successful intravenous injection was often all that could be accomplished, further large doses of serum were given by the intramuscular and, in a few cases, by the intraperitoneal route.

Acute respiratory failure was encountered in several patients during the administration of serum intrathecally, and prolonged artificial respiration had sometimes to be employed. The tendency is well recognised, and is probably caused by anæmia of the respiratory centre due to a fall of blood pressure. This rapid fall of blood pressure is a very frequent consequence of the intrathecal injection of serum. The condition has been specially studied by Sophian.[20]

Fulminating cases due to type 3 organism continued to be admitted. With the serum used, the results of the intravenous injection of large doses were not nearly so good as was found by Herrick and by Banks. Of 11 patients admitted in an acutely ill condition who were given large doses of serum intravenously in addition to serum intrathecally, only three recovered. This gives a death-rate of 73 per cent. for these cases. Nevertheless, it seems to me that failure was due rather to the absence of appropriate antibodies in the serum than to the method used. The largest amount of serum given in any one case was 1110 c.cm.

Subarachnoid lavage with normal saline has been frequently recommended, recently by Whittingham, Kilpatrick, and Griffiths.[21] This method was used intensively in the last two cases, both children, in the present series; both died. When we have to deal with organisms of such virulence the selection of an effective method of treatment is difficult. The method of subarachnoid lavage is worthy of more extensive use. The main objection to it is that it requires much time for its proper performance. It seems that, given a more potent variety of serum, it might be of much assistance in preventing the passage of a case into the post-acute stage with the formation of adhesions. In one case in this series mercurochrome in isotonic glucose was given intravenously on two occasions (15 c.cm. at each injection). It did not appear to be of any value.

Serum phenomena.—A serum rash occurred in eight cases (25·8 per cent.), of which four recovered. In one case it was erythematous and accompanied by joint pains: in the others it was urticarial. Phenomena of anaphylaxis were never seen. Desensitisation was performed if the previous administration of horse-serum was suspected.

MORTALITY AND SEQUELÆ

Of these 31 cases, 12 died within 48 hours of admission. Of the remaining 19 cases, 6 recovered. This gives a death-rate of 68·4 per cent. Many of the 12 cases excluded died within 24 hours after admission. The 6 recovered cases have all been recently examined: 2 have had no complaints, and in these clinical examination was negative. The following is a summary of the condition in the other 4 cases:—

CASE A.—Male, 20 years. Symptoms and signs marked but evanescent; discharged as "forme fruste." Fainted a week after discharge and was unconscious for 24 hours. Headache persisted for two weeks. Clinical examination negative.

CASE B.—Male, 10 years. Symptoms mild. After discharge had an illness which was described as of "rheumatic" type. He still has headache (vertical).

CASE C.—Male, 27 years. Typical acute case. Functional paraplegia and deafness in left ear during convalescence. Nine months later, still nervous with occasional giddiness. Hearing almost absent in left ear. Rinne ÷ ÷. Cremasteric reflexes absent. Extensor muscles of left wrist weak.

CASE D.—Male, 30 years. Acutely ill, with two recrudescences. Received in all 1110 c.cm. of serum. Five months later: still having headaches: deafness in left ear, and numbness in thighs. Stated definitely that he had had aspermatorrhœa since his illness. Gait slightly ataxic; weakness of all leg muscles, and some arm muscles. Cutaneous responses modified in both legs. Right knee-jerk practically absent. Cremasteric reflexes absent. Rinne ÷ ÷ in left ear.

THE RÔLE OF INJURY

Cases in which it can be shown that injury definitely caused the onset of cerebro-spinal fever are rare. Richey and Helmbold[22] published a case in 1923 and reviewed the literature. In 1929 Lode and Schmuttermayer[23] described a case and quoted Korbsch, who, in 1923, could find only 14 authenticated cases recorded. It appears from published cases that, when the onset has been due to injury, there has either been a fracture of the base of the skull or else the symptoms of meningitis have developed within two days; in any case the onset has rarely been later than the fourteenth day.

From the medico-legal aspect the following case is of some interest:—

The patient, a powerfully built miner, aged 52 years, was admitted to hospital on July 21st, 1931. The history was that he had sustained a head injury in the pit on June 4th, 1931. The injury was apparently a scalp wound, and no evidence of fracture had been found. On June 24th he was "signed off" insurance as fit for work. Meningeal symptoms developed on July 19th. His condition was very serious on admission. He became rapidly worse and died on July 24th. After death the relatives alleged that the accident had been the cause of the onset of the cerebro-spinal fever. The coroner ordered a post-mortem examination, which was performed by Dr. J. Crook. Thick pus was found in the ventricles, at the base of the brain, and in the spinal theca; the cranium was shown to have been unaffected by the scalp wound, and there was no evidence of fracture of the skull. The court found that the injury had played no part in determining the onset of the meningitis.

Claude Ker rightly pointed out that during an epidemic of cerebro-spinal fever the tendency is to attribute all head symptoms to minor injuries and, in the case of children especially, it is easy to elicit a history of a recent fall.

A factor which may possibly be of some ætiological importance, and to which attention does not seem to have been drawn previously, is a history of a recent only one case. Two of the 7 cases recovered. Herpes existed together with a typical rash in 4 cases; with a serum rash in 5; with both a specific rash and a serum rash in 3. Of the 7 cases 3 were children, aged 3, 5, and 9 years respectively. This incidence may be compared with that in Robertson's series,[12] where it was never present in 66 patients under 16 years of age; and with that in the series of Collette,[13] where it was found in 15 cases in a series of 48 children.

Temperature and pulse.—Eight cases showed a temperature of over 103° F. immediately before death; in one of these it was 106·6°. In children the pulse-rate was sometimes over 160 before death.

Complications.—Since the death-rate early in the disease was high, complications were few. Pain in the joints occurred in 4 cases (12·9 per cent.), but a typical acute arthritis was not seen. Internal hydrocephalus was marked in one case and slight in two others (one of whom survived). Orchitis or epididymitis was not observed in a single case. The survivors have recently been questioned about this complication, but none has any recollection of pain or swelling in the testicles.

THE CEREBRO-SPINAL FLUID

An increase of tension is a very suspicious feature. In every case, except one, the fluid was under considerable pressure at the initial lumbar puncture. The fluid from practically every case showed a typical clot on standing. In one instance fluid which had previously been very turbid was straw-coloured, and coagulated into a solid mass very rapidly. This was probably an example of Froin's syndrome, which is explained by Hanes [14] as due to an escape of blood plasma into cerebro-spinal fluid contained in a cul-de-sac of the meninges. The patient died.

Xanthochromia.—Under this heading may be included: (*a*) Froin's syndrome; (*b*) erythrochromia—a yellow coloration, due to admixture of the fluid with the altered hæmoglobin set free by previous trauma during lumbar puncture; (*c*) true xanthochromia—found in cases with intrathecal adhesions causing obstruction to the passage of fluids; subsequent lumbar puncture draws off fluid tinged yellow by serum (Chiray [15]). In the present series xanthochromia of some type was noticed 13 times in 7 cases. All these patients except one died. Of these seven cases, one had Froin's syndrome, two probably had erythrochromia, since traces of blood had previously been present in the fluids; and three probably had the true xanthochromia of Chiray.[15] The remaining case showed yellow coloration of the fluid at the initial lumbar puncture; the colour was probably due to admixture with pus, since the fluid later became markedly purulent.

Cellular content.—Initially the total cell count per c.mm. varied between 720 and 31,000. Polymorphs varied between 70 and 97 per cent. (usually slightly over 90 per cent.). It is well known that the differential count varies with the progress of the disease.

Chemical reactions.—Globulin was always in excess. The percentage of albumin varied from 0·05 to 2·4, but was generally between 0·2 and 1. The normal chloride content of the cerebro-spinal fluid is 0·73 per cent. (Linder and Carmichael [16]). In this series the average chloride content was 0·68 per cent. Most readings approximated closely to this, but readings of 0·72 and even 0·78 were also found. The diagnostic value of the chloride content is therefore very doubtful. One case showed partial reduction of Fehling's solution; in all others glucose was absent. The colloidal gold reaction gave a meningitic response in each of three cases examined.

Stained preparations of centrifugalised deposit were examined in every case—often repeatedly. The specific organism was seen in every case except three, and in one of these the meningococcus was isolated in pure culture. The other two cases were of the "forme fruste" type; they cleared up rapidly, but both showed sequelæ, to be described later. In the earlier part of the epidemic diplococci were usually extracellular and scanty; towards the end intracellular forms predominated. The meningococcus was isolated in pure culture in 15 cases—or in 83 per cent. of the cases examined by this method. Much of the chemical and cultural work on the fluids was performed at the bacteriological laboratory of Sheffield University.

SEROLOGICAL TYPES

Cultures were forwarded to Dr. W. M. Scott at the Pathological Laboratory of the Ministry of Health, and in 12 instances the organism was successfully typed. I am very much indebted to Dr. Scott for the *following information*:—

Of the 12 cases, in five the organisms were identified as being of type 3; four as of mixed type 1 and 3; one as of type 1; and in one case the organism was classified as allied to types 1 and 3, but further differentiation was not carried out. The remaining case—a baby of 18 months—showed an organism which was placed in a group including types 2 and 4, and probably other types and "individual" strains. (All the types referred to are Gordon's.)

DIFFERENTIAL DIAGNOSIS

The final diagnosis in 13 cases admitted under th writer's care with a provisional diagnosis of "cerebro spinal fever" was as follows:—

Influenzal pneumonia, 3; broncho-pneumonia, 2; loba pneumonia, 1; broncho-pneumonia with pleural effusion, 1 pneumococcal septicæmia, 1; pneumococcal meningitis, 1 acute tetanus, 1; acute purulent meningitis (otogenic), 1 meningismus (? intestinal), 1; meningismus (unknow origin), 1.

TREATMENT

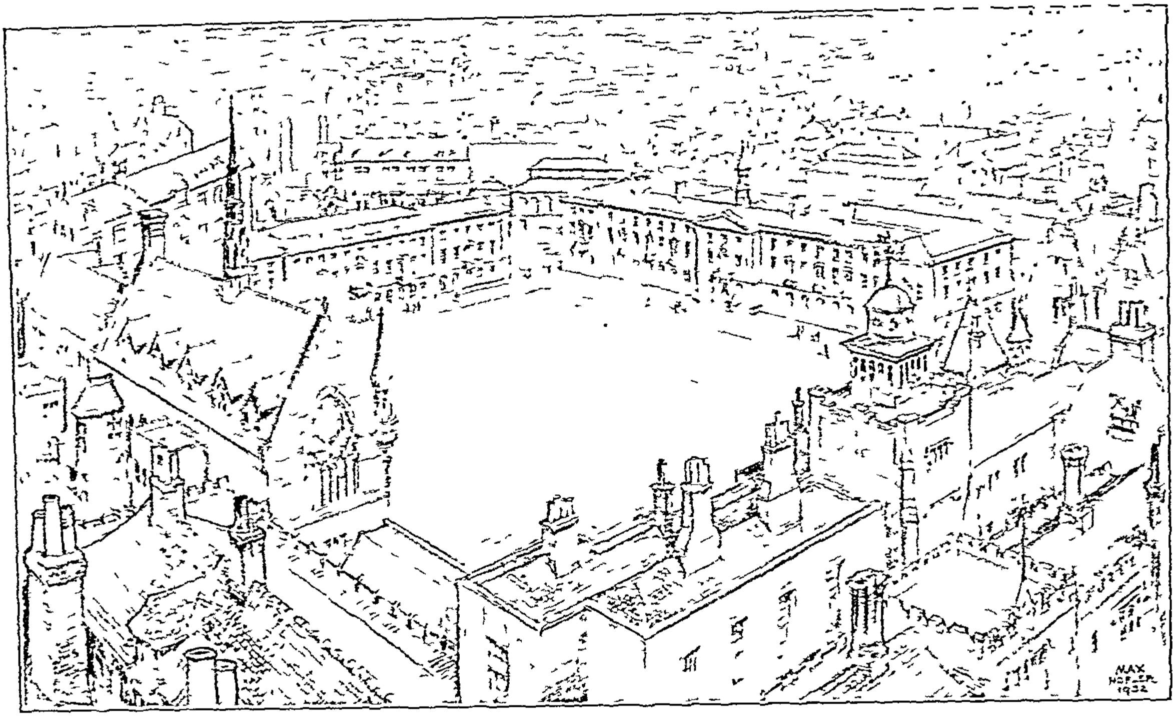
Treatment in accepted cases consisted mainly i repeated withdrawal of cerebro-spinal fluid, togethe with the administration of antimeningococcal serun by the intrathecal, intravenous, intramuscular, o intraperitoneal routes. Except in the last two cases i the series, a polyvalent serum of British manufactur was used throughout.

Lumbar puncture.—The average amount of flui withdrawn by this route was: per puncture, 38 c.cm. per case, 174 c.cm. The greatest amount of flui withdrawn in any one case was 1061 c.cm. Th operation was usually performed under gener anæsthesia, thus increasing the flow of fluid an preventing restlessness during the injection.

The point mentioned by Ker [17] should be stressed—vi the advis [illegible] uccessive lumbar punctur with the [illegible] on the right side and on t left side, [illegible] ge from the ventricle whic is uppermost. This applies especially when the flu from a patient who is obviously ill does not show any pu On several occasions I have turned a child patient whi the trocar was still in the back; this usually resulted in t appearance of a thin stream of pus in the fluid.

Cisternal puncture was carried out on 26 occasions on 22 a good flow was established. The greate amount of fluid withdrawn at any one puncture w 65 c.cm. and the average amount per puncture w 23 c.cm. Serum was given by this route on seve occasions; the usual amount was 20 c.cm., provide that a sufficient excess of fluid had been withdrawn- e.g., 10 to 30 c.cm. General anæsthesia was alwa employed. Cisternal puncture is of considerab importance in diagnosis and treatment. It especially indicated in cases where adhesions in t spinal theca have prevented the withdrawal of flu by lumbar puncture. Serum injected by this rou has ready access to the brain.

Administration of serum.—The earlier cases in t series were treated in the orthodox manner by intr thecal injections of serum every 12 or 24 hours, alo with intramuscular or a single intravenous injectio The dose of serum given intrathecally was usual between 25 and 40 c.cm. Since type sera were n available, early experience suggested that great success might be obtained by increasing the dose the polyvalent serum. Hence, in one case great amounts of cerebro-spinal fluid—e.g., 90 c.cm.—we withdrawn, and amounts of serum up to 80 c.c were given intrathecally. This patient had t



The new medical school as it will appear when completed on the site of Merchant Taylors' School.

Britain, adjoining and belonging to the hospital, and plans were prepared showing that the available area would suffice for the purpose, although the buildings would be cramped and the site not permit of expansion for future needs. The governors of the hospital then suggested the investigation of another site, shortly to become vacant, at Charterhouse, five minutes' walk from the hospital.

The Hospital of the Charterhouse, founded by Thomas Sutton in the reign of James I. after dissolution of the Carthusian Monastery, has been the home of two great public schools. Charterhouse School, where Astley Cooper was brought up, moved out to Godalming in 1872, and three years later Merchant Taylors' School (which had the surgeon Henry Cline among its pupils) moved in from Suffolk-lane, paying, it is said, £90,000 for its new quarters. That school in its turn is now to find wider spaces at Sandy Lodge, near Rickmansworth. The buildings thus left vacant nearly surround the famous quadrangle and form a close on which only the pensioners look out. One of these poor brethren, it may be recalled, was Stephen Gray, who was awarded the Copley medal by the Royal Society for his electrical researches. These historic buildings, with certain alterations, would be available at once to house the departments of chemistry, physics, biology, physiology, and possibly pharmacology, the anatomy department alone requiring a new home. There are suitable refectories and kitchens, and ample room on which a residential college could be built, leaving sufficient space for tennis courts.

The short distance which separates the site from the hospital is regarded as of little consequence compared with the amenities which it provides, both for present needs and for development in the future, and it has been decided by the council of the college that every effort should be made to acquire the Merchant Taylors' School site. A sum of about £200,000 is required to complete the scheme, and as the only available asset is the building which *now houses the physiological department* most of this money must be subscribed. The University of London, of which the college is a constituent institution, is not in a position to make a grant in aid. No public appeal is being issued, but it is hoped that large donations will come in from public-spirited people who appreciate the importance of the training of medical students. Many members of the staff of the college have contributed generously. The matter is urgent. The Merchant Taylors' School site becomes vacant at the end of the year, and an option on it has been obtained until the middle of October.

MEDICINE AND THE LAW

A Coroner on Consent

A CORONER is entirely within his rights in letting it be known that in all cases where death occurs under an anæsthetic he will have a very careful inquiry. The law authorises this *official vigilance*, and the public expects it. When, therefore, at a recent inquest at St. Helens, Lancashire, the coroner announced that he had made up his mind to this general course, the statement was declaratory of existing practice rather than revolutionary. The occasion was an inquest upon the death of a man who, on the advice of his medical attendant, had entered the St. Helens Hospital on August 25th, suffering from cancer of the large bowel. Four days later his condition was complicated by acute obstruction of the bowel. During his night round on the 29th the house surgeon decided that immediate operation was necessary. He called the patient's own doctor; after a joint examination the operation was undertaken, the house surgeon administering the anæsthetic, and the patient's doctor performing the operation. The patient collapsed seven minutes after the head or aural operation. One case in this series gave a history of an operation on the ear two weeks before the onset of meningitis. There was no evidence of mastoiditis on admission. Meningococci were grown from the fluid. The patient died. Perhaps, as McKenzie[24] has pointed out, the organisms may pass from the pharynx to the middle ear via the Eustachian tube. It seems possible that an aural operation may determine the onset of meningitis.

GENERAL REMARKS

This record shows how extremely virulent cerebrospinal fever may be when it becomes epidemic in a community. The great drawback to treatment during this outbreak was the impossibility of obtaining a potent antiserum, due, of course, to the fact that the sera used for some months after the start of an epidemic must be prepared from inter-epidemic strains, which often differ markedly from those actually prevalent during the epidemic. It is well recognised that most epidemics have been due to types 1 and 2 of the meningococcus, and this knowledge has perhaps given a false idea of security. In the present outbreak over 75 per cent. of the cases investigated showed organisms of type 3 or of mixed type 1 and 3; this is a very probable explanation of the high case-mortality rate in the present series. Nevertheless, it must be emphasised that an outbreak such as that described is more or less exceptional nowadays. Serum treatment has been proved in the past to be a most efficacious remedy for what is otherwise a very deadly disease, and to withhold serum in adequate doses must always be a risky procedure.

I have to thank Dr. J. S. Anderson, Dr. William Barr, and Dr. E. L. Sturdee, of the Ministry of Health, for much valuable criticism. I have also to thank Miss C. Barraclough and Miss E. Wilkinson for assistance in the tabulation of data.

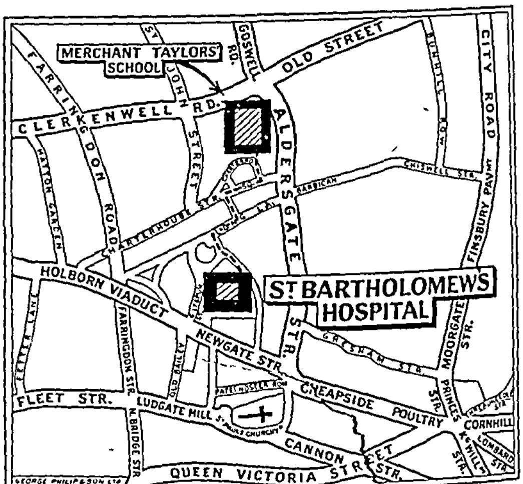
BELFAST MENTAL HOSPITAL.—The report of the medical superintendent of this hospital for 1931 states that whereas, on the basis of official requirements, there was accommodation for 976 patients, the number actually in residence on Dec. 31st was 1390, an excess of 42 per cent. A scheme for the provision of additional accommodation is under consideration.

THE MEDICAL COLLEGE OF ST. BARTHOLOMEW'S HOSPITAL

PROPOSED EXPANSION ON A HISTORIC SITE

St. Bartholomew's Hospital Medical College, founded by John Abernethy and his colleagues about the year 1830, and for long incorporated with the hospital, obtained its own charter in 1921, and became to that extent a separate institution. It is obviously essential for the training of the students, who at present number about 800, that the hospital and college should remain in the closest coöperation for the purpose of clinical studies, and it is agreed that the pathological museum, the library, and the clinical lecture theatres should remain on the hospital site. But the proper housing of other departments of the college in the limited space available in Smithfield has caused anxious thought. The departments for the teaching of pre-clinical subjects could, indeed, be moved elsewhere with advantage both to the hospital and the college. The requirements of the hospital have already displaced the residential college, of which James Paget was the first warden, the room temporarily used by the nursing staff duri rebuilding of the hospital. This rebuildin in the year 1905 with the erection of out-patient department. This was followed in ing years by the erection of a pathological b nurses' home, and a surgical block, provided operation theatres and capable of dealing wit treatment of 250 patients, opened in 1931. governors of the hospital have been cons a lay-out plan for the completion of the rebu in the light of modern requirements, and it become clear that any future buildings for dep ments required for the treatment of pat must further displace buildings hitherto occupie the medical college.



Five minutes' walk from hospital to school through Charterhouse-square.

Two years ago the council of the medical col resolved to house on one site the whole of the p clinical departments, including chemistry, physi biology, anatomy, physiology, and pharmacolog and to build on it a new residential college for studen with adequate provision for recreation. It was first thought desirable to investigate a site in Lit danger of allowing a full cylinder of any compressed gas to pass into inexperienced hands is one which scarcely requires emphasis.

Unregistered Dentist Fined

The substantial fine of £100 (with the alternative of three months' imprisonment in default) was inflicted at Hull last week on a dental mechanic for practising dentistry without being a registered dentist. It was stated that he had been fined on three previous occasions for similar offences. A woman for whom the accused had made an extraction said that she afterwards suffered severe pain; she had since been obliged to attend a qualified dentist for removal of broken pieces of tooth left in her gums. If any members of the public still believe that any unregistered practitioner must have some special skill, they may note that the stipendiary magistrate, in refusing an application for time in which to pay the fine, told the defendant that he was a danger, and should be locked up as long as possible.

A Warning

The Secretary of the Royal Medical Benevolent Fund informs us that a man called at the office of the fund last month who gave his name as Dr. John Alexander Thomson, and stated that he had qualified in 1920. He said that he had been suffering from tuberculosis and had been in Switzerland for treatment for two years, that he had recently been in St. Leonard's Hospital, Shoreditch, and that he was now anxious to go to Liverpool, where he had been offered a post as ship's surgeon for short sea trips on the Cunard Line. Reference to the Medical Register shows that Dr. John Alexander Thomson's name was included from 1920 to 1931, but is omitted in 1932. Inquiry has established the fact that Dr. John Alexander Thomson died at Huddersfield on July 16th, 1931. It would thus appear that an impostor is using the name of a former registered medical practitioner.

THE PUBLIC HEALTH

ANNUAL REPORT OF THE CHIEF MEDICAL OFFICER OF THE MINISTRY OF HEALTH

Sir George Newman's annual report for 1931[1] shows that the falling birth-rate and death-rate have just about cancelled each other out, the population of Great Britain in April, 1931, being 44,790,485. The two principal forms of death, as in previous years, were diseases of the heart (206 per thousand deaths) and cancer (121 per thousand). These are followed by diseases of the nervous system and sense organs (82 per thousand) and tuberculosis of the respiratory system (60 per thousand). Between the ages of 16 and 65 the corresponding figures of these four groups are: 167, 155, 77, and 141. Attention is drawn to the high proportion of deaths from violence and lack of care among illegitimate children (6266 per million) compared with the legitimate (78 per million). There has been an astonishing saving of life during the first 12 months, particularly in deaths from bronchitis, pneumonia, diarrhœa, and enteritis. This is ascribed in large part to increased maternal care, brought about through education of the mother. An important cause of avoidable death is road accidents, the toll of which now stands among the first eight factors of mortality, having risen from 7 to 16 per 100,000 of population within a decade. Suicide constitutes another group of avoidable deaths which has increased since 1920. The suicide-rate increases with age and, if allowance is made for the ageing of the population, it is actually lower than before the war for men though not for women. The statistics show the increasing popularity of coal gas as an agent of self-destruction. There is no evidence that the gloomy months of the year drive people to take their lives; the maximum incidence was found in March, April, and June, and the minimum in November, December, and February.

England and Wales lost during the year a total of 26½ million weeks' work among the insured population from sickness and disability for which benefit was payable.

THE MOTHER AND CHILD

In 1931 2601 deaths were directly due to child-bearing. The puerperal death-rate was 4·11 per thousand live births, the lowest recorded since 1927; the rate for puerperal sepsis was 1·92, and here also a slight decrease is noted. The chief medical officer surveys the recent reports on maternal mortality from the general and regional standpoints.

Under the Local Government Act, 1929, the responsibility of administering Part I. of the Children Act, 1908, was transferred from the poor-law authorities to county and county borough councils and to autonomous maternity and child welfare authorities. These departments had not usually had previous experience of this work, which has sometimes been overlooked and neglected. In most areas the health visitor has been appointed infant life protection visitor, so that all children under the age of 7 are supervised by a trained officer. It is desirable that the health visitor should have special teaching in the supervision of a nurse child, for the work involves ascertainment as well as report on the suitability of the home and the health of the child. An appeal is made to voluntary organisations to find suitable homes.

After the second year of life morbidity replaces mortality as the chief health problem. Despite the increasing use of infant welfare centres, a large proportion of children are still found to be suffering from defects and ailments at the first school medical examination. Mothers have been taught far more about the care of the infant than of the toddler, and there has been little reliable systematic observation of the development of the pre-school child. Arrangements for home visiting are rarely adequate to cope with problems arising during the difficult period of adjustment between infancy and childhood. Provision should be made for both mental and physical care during this period.

At the end of 1931 2680 nurses were engaged in health visiting work. There were some 1000 ante natal centres provided by local authorities and some 200 voluntary clinics; postnatal and gynæcological clinics were insufficient in number. Some 1900 infant welfare centres are under local authorities and over 800 under voluntary bodies; a number of new buildings have been erected for their accommodation, often providing room for the school medical service in addition. Twenty-one day nurseries are provided by local authorities and four times this number by voluntary bodies. Convalescent treatment is available for expectant and nursing mothers and small children in 32 voluntary and 17 municipal homes, while 128 voluntary homes and 5 provided by local authorities take in mothers and babies.

---

[1] H.M. Stationery Office. 1932. Pp. 259. 4s.

anæsthetic was administered, and, in spite of all possible efforts to revive him, he died of heart failure. Fortunately the coroner was able to decide that the doctors acted wisely and well, that the anæsthetic was correctly administered, and that all concerned did everything possible. The word "fortunately" is used because it appears that the medical profession does not enter this coroner's court without a stain upon its character. "I know of a case," he is reported to have remarked during the inquest, "where a woman was suffering from appendicitis symptoms. The symptoms were so acute that it was deemed necessary that there should be an immediate operation. The woman was sent to a certain institution where an operation for appendicitis was performed. It was found that the appendix was as sound as I hope mine is. They made an incision to see if there was any abdominal trouble, and there was none. The woman had pneumonia, and died from pneumonia. The only way they saved their skins was that the police surgeon said that the pains from pneumonia were somewhat similar to those of appendicitis." In so far as this anecdote might convey the fixed opinion that members of the medical profession are more anxious to save their own skins than their patients' lives, the result of the inquest was fortunate indeed.

At an earlier stage of the proceedings the coroner had pressed witnesses with questions whether consent had been given to the operation. The widow in particular was more than once asked whether her consent had been invited. All the poor woman could answer was: "They never asked for my consent; I never said 'Don't do it'; I thought it would save him." She said she was satisfied that the doctors had done their best; her husband had been in terrible pain. The circumstances of the case might have been thought sufficient to justify the application of the legal maxim that all things are deemed to have been done in proper form unless there is any element which suggests the contrary. The coroner, however, continued to press his point. The house surgeon, who had given evidence that the dead man's own medical attendant (presumably in close touch with the patient and his family) had concluded that the operation was necessary. "You don't know," he was asked, "whether the man's condition was explained to him or whether he gave consent?" His answer was in the negative, and when the coroner further asked, "Who can satisfy me that this man consented to the operation?" it is reported that there was no reply. Thereupon the coroner is reported to have said: "I want you and all medical practitioners to realise what you ought to do. You should explain to the patient that you are of the honest opinion that an operation is the only thing that can save his or her life. You should explain the whole thing from beginning to end, and you should say to the patient, 'Do you consent to the operation being performed?' If I was a medical man, I would get the patient to sign an assent, or if he was in such agony or so abnormal so far as his brain was concerned, I would get someone on his behalf to do it. Then you ought to say: 'You are going to have this operation performed; it is necessary to have an anæsthetic administered; are you satisfied that it should be administered?' It seems to me very clear what medical men ought to do."

In the face of these observations it may be useful to make the comment that, although technically any surgical operation is an assault unless performed with consent, no jury would hesitate to infer consent where a patient has placed himself in the hands of his medical attendant, has entered a hospital for the purpose of such remedy or cure as modern medical science affords, and has undergone an urgent operation to save life without any suggestion of objection from the patient himself or from his relatives. Every doctor knows the duty of explaining the nature and possible consequences of the treatment recommended; advice to this effect is given in "The Conduct of Medical Practice." But the medical profession need not take too seriously the vision of extreme precautionary formalities, the written agreements engrossed, stamped, attested, or otherwise, and the solemn procession of attendant lawyers and notaries public.

Milk Prosecution: the Freezing Test

A farmer was prosecuted at Taunton on Sept. 3rd for having on May 23rd last sold milk containing 8 per cent. of added water, to the prejudice of the purchaser. A witness for the defence said that the freezing test which had been applied to the milk sample, on which the prosecution apparently relied for proof of adulteration, had been found to vary considerably. He had tested milk from cows on the same farm in August, and had found the freezing point to be below the percentage average given by the prosecution. The witness said there was no positive test for detecting added water in milk. On behalf of the farmer it was contended that the prosecution should not have been proceeded with when the Government chemist's certificate stated that the results of his analysis did not form evidence of the presence of added water. The summons was dismissed with costs against the prosecution.

Exposure of Infectious Patient

A Cheshire miner suffering from diphtheria was taken to a sanatorium. He was later found at home in the company of his wife and sister; he refused to go back to hospital, and was consequently isolated at home. Two days later he went back to the hospital, but after a few days he ran away once more. The law provides a penalty for persons who, suffering from a dangerous and infectious disorder, expose themselves in public without proper protection. Under this provision the man has been fined 20*s.* on each of two summonses alleging unlawful exposure on two dates in June. The folly and the risks of such conduct form a lesson which might well be taught in all schools.

Gas Cylinder Explosion

An inquest was lately held at Farnborough, Kent, upon the death of a contractor's carman who died after injuries received from the explosion of a gas cylinder. The deceased was in charge of a dust-cart and, while collecting house refuse in the course of his duties, was asked by a doctor's wife to clear away a few cylinders which had been lying about for a long time. A few minutes later a fellow-workman heard an explosion and, returning to the cart, found the man on the ground with an empty cylinder near him. The sanitary inspector of the local authority said the dustmen had strict instructions as to things they should not handle. Had he himself been present, he would have refused to allow the man to take the cylinders away. He believed the deceased meant to take the brass caps off the cylinders as there was a ready market for brass; he understood that a dealer called at the dustmen's homes every week. The jury returned a verdict of death by misadventure. The

THE MEDICAL REGISTER:

UNTRACEABLE PRACTITIONERS IN 1932

WE are asked by the Registrar of the General Medical Council to publish the following list of medical practitioners who have not replied to his inquiries as to the accuracy of their addresses. Anyone, wherever resident, who finds his or her name included in this list should communicate immediately with the Registrar, 44, Hallam-street, Portland-place, London, W. 1, otherwise the name will be omitted from the next issue of the Medical Register. There may be some who have replied while this list was in the press. The date given is that of registration; the qualification is the principal one registered. The letters (E), (S), and (I) denote registration at the English, Scottish, or Irish branches respectively; (Col) and (For) denote registration in the Colonial and Foreign Lists of the Register. Those marked (S) should communicate direct with the Registrar of the Scottish Branch Council, 12, Queen-street, Edinburgh.

INFECTIOUS DISEASES

There was a great reduction in the prevalence of small-pox, bearing out the impression that the disease increases in any district for four or five years and then declines. There was also a substantial decrease in enteric fever. Diphtheria immunisation has become much more popular and has given strikingly good results; unfortunately no such claim can yet be made for immunisation against scarlet fever. The value of convalescent serum in preventing and treating measles is now placed beyond doubt. One of the outstanding epidemiological features of the year was the rise in the incidence of cerebro-spinal fever, following that of the previous year. There was a continued decline in acute poliomyelitis and encephalitis lethargica. The influenza epidemic of the year was mild and showed no unusual features.

The total number of deaths from tuberculosis was 35,818. There has been a decline in the death-rate from all forms, though in varying degrees. The Ministry attach great importance to the ascertainment of all cases; in most cases, it is held, the source of infection can be traced if contacts are examined. A negative reaction to tuberculin is reliable and useful in eliminating suspects. Tuberculosis schemes are in a stage of transition at the present time, but increasing use is being made of dispensaries and of beds for observation. Artificial light is held to have a definite importance in treatment. The Ministry has investigated the salt-free diets recommended in Germany, but finds that they are expensive, involve administrative difficulty and expense, and are disliked by the patients. Their value is insufficiently established to justify extended trial.

The mortality for rheumatic fever shows a gratifying decrease in 1931, and a decrease in the death-rate from heart disease in the younger age-groups is also recorded; the continued high figure for heart disease is largely fictitious, being due to the increase in the age of the population and to the change in the form of death certificates. The research and clinical work carried on during the year on acute and chronic rheumatism is reviewed.

At the end of 1931 189 venereal disease treatment centres were available; a number of centres have increased their facilities for treatment. It is not yet possible to estimate accurately the amount of delay in seeking advice, but in centres where accurate figures are kept a gratifying improvement in the promptitude with which the men come for treatment is noticed, though women still delay. Nevertheless, there is a decline in syphilis in women, which is ascribed to increased education. There seems to be no reduction in the amount of gonorrhœa in the country. Experiments in the use of vaccines suggest that, except at the early stages, the titre of the complement-fixation reaction can be raised considerably by a vaccine, and at the same time the organisms disappear.

FOOD AND DRINK

The work of the Ministry in relation to individual and national health and the safeguarding of food from deficiency, adulteration, and transmissible disease is discussed. About 15,000 cattle were included in licensed herds during 1931. The double intradermal tuberculin test, although it has been strongly criticised, has been found to be much more reliable in skilled hands than have other methods. Laxity in complying with the regulations has been the cause of disaster in several herds; it may be necessary to adopt more severe penalties and to revise the regulations to include more frequent testing of certain herds. No herd owner can hope to attain or retain a designated milk licence if he attempts to immunise his cattle by the use of a vaccine, for every animal will react to the tuberculin test.

The jam standards adopted recently by the Food Manufacturers' Federation have been widely criticised as unduly low. Sir George Newman says that the tendency in the jam trade in recent years has undoubtedly been to reduce the amount of fruit and to rely on "improved" methods of manufacture to retain the appearance, consistency, and taste of the older "home made" article. Strictly speaking, the insignificant proportion of expensive whole-fruit jam is the only jam entitled to the term "first class" or "full fruit standard." The practice of polishing apples with a very thin film of paraffin wax seems to be harmless and is said to preserve the fruit. A more doubtful practice is the dyeing of oranges to improve their colour; when dye conceals unripeness or inferiority its use may be an infringement of the Food and Drugs Act, 1928.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Lt. W. M. Greer is transferred to the Permanent List.

Surg. Lt. (D) W. E. L. Brigham to be Surg. Lt.-Comdr. (D).

W. P. Culbertson to be Surg. Lt.

The following appts. are notified: Surg. Comdrs. E. L. Markham to *Pembroke*, for R.N. Barracks; N. A. H. Barlow to *Cairo*, and as squadron medical officer; G. E. Heath to *Excellent;* H. L. Peregrine to *Victory*, for R.N. Barracks; J. D. Bangay to *Hawkins;* J. C. Brown to *Royal Sovereign;* M. B. Macleod to *Malaya;* L. A. Moncrieff to *Victory*, for Portsmouth; and T. G. B. Crawford to *Pembroke*, for R.N. Barracks.

Surg. Lt.-Comdrs. (D) D. Barker to *Pembroke* for R.N. Barracks, Chatham; A. D. McHaffie to *President*, addl., for course; and W. E. A. Sampson to *Pembroke*, for R.M. Infirmary, Deal.

Surg. Lts. J. B. W. Rowe to *Victory*, for R.N. Barracks; J. G. Lynch to *Vivid*, for R.N. Barracks; and H. S. Marks to *Pembroke*, for R.N. Barracks, Chatham.

Surg. Lts. (D) P. S. Turner to *Victory*, for Haslar Hospital; L. F. Fairey to *Sandhurst;* and A. W. Y. Price to *Sussex*.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt. W. Lennon is appointed to *Victory*, for R.N. Hospital, Haslar.

ROYAL ARMY MEDICAL CORPS

Lt. R. D. MacRae resigns his commn.

RESERVE OF OFFICERS

Lt.-Col. B. S. Bartlett, having attained the age limit of liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY

Capt. D. J. Davies to be Maj.

Lt. E. G. Mackie (late R. Scots) to be Capt., and relinquishes the rank of Lt.

INDIAN MEDICAL SERVICE

The undermentioned officers have vacated appts. in India: *A.D.M.S.:* Maj.-Gen. T. G. F. Paterson. *D.A.D's.P.:* Maj. L. Dunbar, R.A.M.C., and Maj. N. T. Whitehead, R.A.M.C.

The undermentioned appts. have been made: *D.A.D.M.S.:* Maj. R. D. Cameron, R.A.M.C. *A.D.P.:* Maj. L. Dunbar, R.A.M.C.

ROYAL AIR FORCE

Dental Branch.—The undermentioned are granted non-permanent commissions as Flying Officers: H. Keggin and V. H. Weeks.

COLONIAL MEDICAL SERVICE

Dr. H. D. Weatherhead (Assistant Medical Officer, British Guiana) has been apptd. Supernumerary Medical Officer, Leeward Islands.

THE MEDICAL REGISTER:

UNTRACEABLE PRACTITIONERS IN 1932

WE are asked by the Registrar of the General Medical Council to publish the following list of medical practitioners who have not replied to his inquiries as to the accuracy of their addresses. Anyone, wherever resident, who finds his or her name included in this list should communicate immediately with the Registrar, 44, Hallam-street, Portland-place, London, W. 1, otherwise the name will be omitted from the next issue of the Medical Register. There may be some who have replied while this list was in the press. The date given is that of registration; the qualification is the principal one registered. The letters (E), (S), and (I) denote registration at the English, Scottish, or Irish branches respectively; (Col) and (For) denote registration in the Colonial and Foreign Lists of the Register. Those marked (S) should communicate direct with the Registrar of the Scottish Branch Council, 12, Queen-street, Edinburgh.

INFECTIOUS DISEASES

There was a great reduction in the prevalence of small-pox, bearing out the impression that the disease increases in any district for four or five years and then declines. There was also a substantial decrease in enteric fever. Diphtheria immunisation has become much more popular and has given strikingly good results; unfortunately no such claim can yet be made for immunisation against scarlet fever. The value of convalescent serum in preventing and treating measles is now placed beyond doubt. One of the outstanding epidemiological features of the year was the rise in the incidence of cerebro-spinal fever, following that of the previous year. There was a continued decline in acute poliomyelitis and encephalitis lethargica. The influenza epidemic of the year was mild and showed no unusual features.

The total number of deaths from tuberculosis was 35,818. There has been a decline in the death-rate from all forms, though in varying degrees. The Ministry attach great importance to the ascertainment of all cases; in most cases, it is held, the source of infection can be traced if contacts are examined. A negative reaction to tuberculin is reliable and useful in eliminating suspects. Tuberculosis schemes are in a stage of transition at the present time, but increasing use is being made of dispensaries and of beds for observation. Artificial light is held to have a definite importance in treatment. The Ministry has investigated the salt-free diets recommended in Germany, but finds that they are expensive, involve administrative difficulty and expense, and are disliked by the patients. Their value is insufficiently established to justify extended trial.

The mortality for rheumatic fever shows a gratifying decrease in 1931, and a decrease in the death-rate from heart disease in the younger age-groups is also recorded; the continued high figure for heart disease is largely fictitious, being due to the increase in the age of the population and to the change in the form of death certificates. The research and clinical work carried on during the year on acute and chronic rheumatism is reviewed.

At the end of 1931 189 venereal disease treatment centres were available; a number of centres have increased their facilities for treatment. It is not yet possible to estimate accurately the amount of delay in seeking advice, but in centres where accurate figures are kept a gratifying improvement in the promptitude with which the men come for treatment is noticed, though women still delay. Nevertheless, there is a decline in syphilis in women, which is ascribed to increased education. There seems to be no reduction in the amount of gonorrhœa in the country. Experiments in the use of vaccines suggest that, except at the early stages, the titre of the complement-fixation reaction can be raised considerably by a vaccine, and at the same time the organisms disappear.

FOOD AND DRINK

The work of the Ministry in relation to individual and national health and the safeguarding of food from deficiency, adulteration, and transmissible disease is discussed. About 15,000 cattle were included in licensed herds during 1931. The double intradermal tuberculin test, although it has been strongly criticised, has been found to be much more reliable in skilled hands than have other methods. Laxity in complying with the regulations has been the cause of disaster in several herds; it may be necessary to adopt more severe penalties and to revise the regulations to include more frequent testing o certain herds. No herd owner can hope to attai or retain a designated milk licence if he attempts t immunise his cattle by the use of a vaccine, for ever animal will react to the tuberculin test.

The jam standards adopted recently by the Foo Manufacturers' Federation have been widely criticise as unduly low. Sir George Newman says that th tendency in the jam trade in recent years ha undoubtedly been to reduce the amount of fruit an to rely on "improved" methods of manufactur to retain the appearance, consistency, and taste of th older "home made" article. Strictly speaking, th insignificant proportion of expensive whole-frui jam is the only jam entitled to the term "first class or "full fruit standard." The practice of polishin apples with a very thin film of paraffin wax seem to be harmless and is said to preserve the fruit. more doubtful practice is the dyeing of oranges t improve their colour; when dye conceals unripenes or inferiority its use may be an infringement of th Food and Drugs Act, 1928.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

Surg. Lt. W. M. Greer is transferred to the Permanent Lis

Surg. Lt. (D) W. E. L. Brigham to be Surg. Lt.-Comdr. (D W. P. Culbertson to be Surg. Lt.

The following appts. are notified: Surg. Comdrs. E. Markham to *Pembroke*, for R.N. Barracks; N. A. Barlow to *Cairo*, and as squadron medical officer; G. Heath to *Excellent;* H. L. Peregrine to *Victory*, for R. Barracks; J. D. Bangay to *Hawkins;* J. C. Brown *Royal Sovereign;* M. B. Macleod to *Malaya;* L. A. Moncrie to *Victory*, for Portsmouth; and T. G. B. Crawford *Pembroke*, for R.N. Barracks.

Surg. Lt.-Comdrs. (D) D. Barker to *Pembroke* for R. Barracks, Chatham; A. D. McHaffie to *President*, addl for course; and W. E. A. Sampson to *Pembroke*, for R. Infirmary, Deal.

Surg. Lts. J. B. W. Rowe to *Victory*, for R.N. Barracks J. G. Lynch to *Vivid*, for R.N. Barracks; and H. S. Mar to *Pembroke*, for R.N. Barracks, Chatham.

Surg. Lts. (D) P. S. Turner to *Victory*, for Haslar Hospita L. F. Fairey to *Sandhurst;* and A. W. Y. Price to *Susse*

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Lt. W. Lennon is appointed to *Victory*, for R. Hospital, Haslar.

ROYAL ARMY MEDICAL CORPS

Lt. R. D. MacRae resigns his commn.

RESERVE OF OFFICERS

Lt.-Col. B. S. Bartlett, having attained the age limit liability to recall, ceases to belong to the Res. of Off.

TERRITORIAL ARMY

Capt. D. J. Davies to be Maj.

Lt. E. G. Mackie (late R. Scots) to be Capt., and relinquish the rank of Lt.

INDIAN MEDICAL SERVICE

The undermentioned officers have vacated appts. India: *A.D.M.S.:* Maj.-Gen. T. G. F. Patterso *D.A.D's.P.:* Maj. L. Dunbar, R.A.M.C., and Maj. N. Whitehead, R.A.M.C.

The undermentioned appts. have been mad *D.A.D.M.S.:* Maj. R. D. Cameron, R.A.M.C. *A.D.P.* Maj. L. Dunbar, R.A.M.C.

ROYAL AIR FORCE

Dental Branch.—The undermentioned are granted no permanent commissions as Flying Officers: H. Kegg and V. H. Weeks.

COLONIAL MEDICAL SERVICE

Dr. H. D. Weatherhead (Assistant Medical Officer, Briti Guiana) has been apptd. Supernumerary Medical Offic Leeward Islands.

stands in the way of the completion of the scheme. That the present scheme has extended slowly is perhaps all for the best, as this tends to promote a desire on the part of those areas not included to partake of the benefits of a complete dental service."

Throughout his report Dr. J. A. Fairer indicates that the education committee are getting good value for their outlay. Routine work is being carried out efficiently, and the encouragement given to research fosters enthusiasm. The examples of such work in the present report have not been cut down on the plea of the cost of printing. They include a note on myopia which amplifies an Ealing report on the same subject by recording 38 obstinate cases of blepharitis cured by correction of minor refractive errors. Dr. Constance Walters thinks the chronic inflammation is kept up by the strain of accommodation, and it is apt to occur with hypermetropia of two dioptres or less, because it is in these cases that accommodation will give normal vision, and therefore the strain is maintained. An investigation by Dr. David Anderson deals with the relation between scarlet fever and other defects, especially enlarged tonsils and adenoids. Analysing the records of 1520 children he deduces that enlarged tonsils and/or adenoids increase the liability to scarlet fever, and that scarlet fever tends to cause enlarged tonsils and/or adenoids, or at least to make a pre-existing enlargement more permanent. A thoughtful discussion by Dr. K. Cowan on the orthopædic scheme as a preventive service concludes:—

> "The scheme should embrace all departments of the health services of the area—maternity and child welfare schools, tuberculosis, &c.—and all the agencies of ascertainment in each department should be coördinated under a single control. A much greater return will be obtained from expenditure on an organisation for prevention than upon that for treatment, and a higher proportion of the money allocated for orthopædics might with benefit be diverted for this purpose. At the best the treatment of crippling defects is an expensive burden upon the local authority. The only means of alleviating this burden is concentration of effort on prevention, and in all phases of the orthopædic scheme the essence of prevention is early ascertainment."

In the aggregate of these contributions there is an addition to our knowledge of real economic value.

Wiltshire

There is in this county no open-air school in the strict sense, but part of the Marlborough public assistance institution has just been opened as convalescent accommodation for children, and it is stated, "this provision has already been the means of re-establishing health for many children who were otherwise drifting into chronic disability." Rheumatic heart clinics are active in the county, and when it is remembered that rheumatic and heart affections cause more loss of working time in the industrial world than strikes, it is evident that this work is of economic value. Direct proof of a good return is given in an investigation by Dr. Janet McKay of the after-history of 82 cases treated at the Bath Orthopædic Hospital between 1924 and 1931. The results were:—

	School cases.	Over school age.
Cured	7	7
Much improved	9	24
Improved	11	20
Stationary	2	2
Total	29	53

The classification errs on the side of modesty and the real value is brought out by studying the details which show the practical changes brought about. Few of the cases would have had educational or industrial capacity without treatment, whereas now all the children are attending school and all the adolescents have been working except those marked stationary, which comprise 2 cases of spastic paralysis, 1 of them hopelessly mentally deficient, and 2 cases where treatment was refused. Only 8 of the 53 adolescents have to wear any appliance, and one of these is an artificial limb for a case of sarcoma of the tibia.

MENTAL HOSPITAL REPORTS

The West Sussex County Mental Hospital at Chichester housed 932 patients on Dec. 31st last. Of the 186 admissions during the year, 29 were voluntary, but no temporary patients were received. The hospital is not at present overcrowded. The recovery-rate was 36·5 per cent. and the death-rate 5·6 per cent. Apart from a few cases of influenza, the health was good. The handicraft department continues to provide occupation for patients who cannot be interested in any other way. Parole beyond the estate was given to 16 men and 12 women, and within the grounds to 20 men and 26 women. Five male and four female wards are administered on the open-door principle. An out-patient clinic has been started at the Royal West Hospital at Chichester, in addition to that at the Worthing Hospital. During the year four attendants and eight nurses passed the final examination of the R.M.P.A., and two nurses *became State registered.*

The Isle of Wight County Mental Hospital at Whitecroft had 329 patients in residence on Feb. 3rd, 1932. The recovery-rate for the year was 40 per cent. and the death-rate 9·56 per cent. Apart from three cases of erysipelas, there was no serious infectious disease. The occupational therapy department continues to flourish, and the open-door system is to be adopted. The dental clinic continues to do satisfactory work, and three clinical rooms for therapeutic conversation have been established. The committee hope to establish an out-patient clinic at Ryde before long, and in the meantime the medical superintendent sees at the hospital any case referred to him by medical practitioners.

At the City of Cardiff Mental Hospital there were 777 patients resident on Jan. 1st, 1932; of these 123 were voluntary and 11 were temporary. The recovery-rate for the year was 41·6 per cent., and the death-rate 10·6 per cent. The general health was good, the only infectious or germ-borne diseases being five cases of tuberculosis. The medical superintendent welcomes the new Act which allows the admission of voluntary patients, and cites the case of a man who had invariably suffered three months' misery at home before a minimum period of six months in hospital during his attacks, but who presented himself as a voluntary patient at the very outset of the next attack after the Act, and was discharged recovered in three months. The value of team work is also stressed, an illustrative case cited being the recovery of a patient with a toxic psychosis after pus had been drained from the nasal sinuses by the rhinologist and a vaccine had been prepared by the pathologist. The out-patient clinic continues to do good work; the total attendances during 1931 were 865. A large number of patients have been admitted to the hospital from the clinic on a voluntary basis. A social worker was appointed in May, and her work has proved of the utmost value. Further developments have taken place in the occupational therapy department, and two discharged patients have been appointed voluntary assistants to the occupational therapy officer. Of the male patients 78 per cent., and of the female 87 per cent., are employed in useful tasks. A considerable output of research from the laboratory is recorded. Among the results are that the interference of narcotics with the oxidation of glucose or lactic acid is directly related to their hypnotic power, and that sulphur therapy is worth a trial in schizophrenia. Radiographic examinations of the sinuses were made in 26 cases during the year, and 47 other patients were examined by X rays for various reasons. The dentist attended fortnightly. Short leave of absence was granted to 171 patients on 1226 occasions. Of the nursing staff 18 men and 34 women are registered or certificated.

PUBLIC HEALTH SERVICES

The Economics of Voluntary Work

SPECULATION is busy on the contents of the expected report on economy in public services. Curtailment in the activities of any particular department will no doubt be preceded by careful consideration and will follow an ordered and regulated method. Action is complicated by the fact that many of the social services had their origin in voluntary organisations which have become assimilated in greater or less degree with the public health authority. An outstanding example of what can be done by voluntary work on a large scale is to be found in London, where the movement for maternal and infant welfare was initiated by voluntary effort and still employs very large numbers of volunteers, with an almost incredible saving, not only in official salaries, but in expenditure on poverty and destitution which almost always accompanies ill-health amongst the poor, and which would otherwise be added to the already heavy burden of the ratepayer. In the social work arising out of the school medical service there is an army of 5–6000 men and women, unpaid officials working under 150 trained organisers, and saving the London ratepayers many thousands of pounds yearly. The following-up of children who require treatment or special observation, for example, is carried out by the school care organisation, which is largely composed of volunteers whose work is coördinated by trained workers. Miss Helen Nussey, writing in the annual report for 1931 of the school medical officer to the Council, remarks :

> "When the Council decided to give an opportunity for the coöperation of the private citizen in work for the community by delegating to children's care committees certain of its duties, the trail had already been blazed by voluntary workers who had banded together to work for children in the poorest schools . . ."

The care committees undertake three important duties : (1) They see that no child in need of food is unprovided for ; (2) that no child found by the school doctor to need treatment fails to receive it ; and (3) that no child leaves school in ignorance of the possibilities the district offers of suitable employment, further education, and social recreation. These workers, coming into contact with the home conditions of school-children and their parents, are the means of preventing a large load of chronic invalidism, with its corollary of destitution and State relief, by arranging for the early treatment of disease and effects. From their contact with a wider environment they can also very often readjust employment to the individual and, in some instances, are able to find work for the unemployed by bringing employer and employee together.

In addition to the devotion of individual voluntary workers, the Council, of course, receives the help of voluntary organisations, such as the S.P.C.C., the I.C.A.A., and the special departments at various voluntary hospitals. During the past year the Shaftesbury Society offered their camp school in Epping Forest to be used for parties of children from day schools for the mentally defective ; the success of this experiment has already been noted in our columns. Another example of organised voluntary effort appears in the special dental centre at Hackney Wick, maintained by the Manor Charitable Trust. Intensive work has been carried out there during the year in connexion with children from two of the Council's schools ; a dental hygienist is attached to this clinic, and a follow-up system of letters and visits to parents who refuse treatment has resulted in a very low percentage of final refusals. The report of Mr. A. T. Pitts of an independent inspection of children from the Wick clinic and children attending the usual dental centres of the Council, indicates clearly that the children from the Wick clinic showed a better dental condition—testimony to the value of voluntary effort. When curtailment of social services is being considered, it is to be hoped that there will be no discouragement of such work, but that a concerted effort will be made to stimulate an interest in the public health services amongst understanding people with time to spare. The example of London might well be followed by provincial areas where resources of this nature remain untapped.

SCHOOL MEDICAL REPORTS

County of Leicester

THE county authorities are evidently shrewd economists, neither lavish nor blindly cheese-paring. Like others they realise they are obliged to limit expenditure, however reluctantly. For example, the senior dentist, Mr. Percy Ashton, regrets that a relative inadequacy of his staff has led to a lessening of the conservative work and an increase of extractions of permanent teeth.

> "Until such time as every school in the county is periodically visited and every child receives systematic treatment, the number of permanent teeth extracted will remain comparatively high. The committee are fully alive to this fact and only the present financial situation

the central fund and to limit the remuneration definitively to the amount of chemists' accounts. Payment of these in full would be guaranteed, but it would entail a reduction of ½d. in dispensing fees. The second suggestion is for the central fund to be retained, but some limitation imposed upon the maximum amount payable to chemists in any year in excess of the sum required to pay their accounts in full. The Minister suggests that one-half the surplus should go to dispensing fees, the other half to insurance funds. Whatever terms are finally adopted will be subject to the emergency deduction of 10 per cent. from the central fund so long as the emergency continues.

Dispensing by an Unqualified Chemist

An insurance committee in the Midlands has lately considered a question of a breach of the terms of service by the dispensing of prescriptions on the part of a firm carrying on the business of chemists and druggists, but not employing a qualified person. The law requires health insurance prescriptions to be dispensed by or under the direct supervision of a registered pharmacist or by a person who, for three years immediately prior to Dec. 11th, 1916, had acted as dispenser to a practitioner or a public institution. The firm in question was without its superintendent chemist through his ill-health, from April to June 8th. During that period no qualified person was employed and the managing director seems to have been responsible for the bulk of the 167 health insurance prescriptions undertaken; 93 of these contained scheduled poisons. The managing director admitted the facts. He said he had been unable to obtain a locum tenens; he had been expecting his superintendent chemist back daily; he had himself had eight years' experience and had occasionally had the help of a friend who was a qualified chemist. The pharmaceutical service subcommittee reported that the facts disclosed a serious and dangerous breach of the terms of service by the firm. It was recommended that the Minister of Health be advised to withhold a sum of £50.

CORRESPONDENCE

SPLENECTOMY FOR SPLENO-MEDULLARY LEUKÆMIA

To the Editor of THE LANCET

SIR,—In your last issue (p. 594) Dr. Hildred Carlill gave a preliminary account of a patient whose spleen was removed for spleno-medullary leukæmia three months ago. I can add a note on a case of longer duration. In January, 1922, I saw a man, aged 48, shortly after a large hæmatemesis and melæna; a day later the spleen was palpable and a blood count showed a marked polymorphonuclear leucocytosis with a slight secondary anæmia; white cells 36,000, and a few weeks later 13,600. In March, 1922, he was admitted to University College Hospital under the care of Dr. Batty Shaw, the spleen being still palpable and the white cell count 9125. The Wassermann test was negative, a barium meal showed nothing abnormal.

An exploratory laparotomy was undertaken by Mr. Raymond Johnson, which confirmed an enlarged spleen free of adhesions; the liver appeared normal, and the patient was discharged to have his spleen X rayed once a month. Further attacks of hæmatemesis and melæna took place, the spleen was enlarging, and at my request Sir John Bland-Sutton removed it about March, 1924, finding no adhesions or great enlargement of the splenic vessels, and there was no hæmorrhage. The exact weight of the spleen I do not remember, but previous to the operation it had reached towards the umbilicus. During convalescence the patient ran a high temperature due to a chronic superficial streptococcus infection, with hæmolytic streptococci in the stools. About May, 1924, the patient saw Sir Aldo Castellani, who had seen him earlier in his illness, and he diagnosed leukæmia. A complete blood count showed—

	White cells.*	Red cells.*	Hb.†		White cells.*	Red cells.*	Hb.†

* thousands. † per cent.

(*a*) Neutrophil, 600; basophil, 600; eosinophil, 400.
(*b*) Neutrophil, 1288; basophil, 392; eosinophil, 0.
(*c*) Neutrophil, 1700; basophil, 232; eosinophil, 0.
(*d*) Neutrophil, 11,520; basophil, 720; eosinophil, 0. There were about 11,000 nucleated reds per c.mm.

The patient died in October, 1931, following an intestinal hæmorrhage and hæmatemesis. Apart from œdema of the legs there were no complications. X rays to the long bones, arsenic by mouth and injection, benzol in capsules, and an autogenous vaccine formed the treatment. After the removal of the spleen no further hæmorrhages occurred until just before the termination of life. Throughout the patient got about in comfort without undue signs of distress, with an excellent pulse, but marked pallor.

The course of the disease was approximately nine years and nine months in contrast to the more usual prognosis of about two or three years or less, whilst a maximum duration of ten years has been recorded. In my opinion removal of the spleen in the disease, more commonly practised elsewhere, had a good effect in cessation of the hæmorrhages which initially had been moderately severe.

I am, Sir, yours faithfully,
H. AUSTIN WILLIAMS, M.D. Camb.
Kew-road, Sept. 10th, 1932.

PYRETIC TREATMENT

To the Editor of THE LANCET

SIR,—The letter of Dr. H. W. Hales in your issue of Sept. 3rd (p. 542) presents a strong case for the use of artificially-procured pyrexia in the treatment of one form of chronic ill-health. Deficient cutaneous blood-supply such as he mentions is met with in other forms of disease. As a general or local phenomenon it is found in all forms of "rheumatism," except acute rheumatic fever; in these disorders also a low mouth temperature is constantly found. It is permissible to assume that the hypopietic state is due to one or both of two causes: disturbance of medullary centres, or interference with the physics of the circulatory tubes. These main factors may in turn be influenced by a number of causes among which toxic bodies and local traumata may be found. Any measures productive of a quickened flow of blood and lymph and an elimination of waste bodies by the sweat glands must therefore be as beneficial in disorders of blood pressure as they are in disorders of the skeletal muscles and ligaments.

Pyretic treatment by Neyman's method of diathermy and the electric blanket has, however, certain disadvantages which militate against its

PANEL AND CONTRACT PRACTICE

Agenda of the Panel Conference

THE annual conference of local and medical panel committees will be held in London at the B.M.A. House on Thursday, Oct. 20th, and the elections for representatives to attend this conference will be taking place shortly. The conference discusses as its agenda the report of the Insurance Acts Committee 1931–32, which appeared in the supplement to the *British Medical Journal* of August 20th. Some of the items in this report deserve special attention.

CAPITATION FEES

A special subcommittee has been at work on this matter collecting figures of attendance, and opinions have been invited from practitioners and panel committees on aspects of their work other than the number of attendances. The present capitation fee was fixed in 1924 by a court of inquiry, and the object of this committee is to determine whether the amount then awarded is now considered to be adequate and, if not, the detailed reasons for such an opinion; also how and to what extent the content of the medical service under the Acts has increased since 1924. This is not quite so simple as it looks. To take an example: the injection treatment of varicose veins was not held in 1924 to be within the Act; now it is. This is held by some to mean more work for the same capitation fee; on the other hand it may mean less treatment of bad legs and varicose ulcers. A matter rather difficult to prove.

FEES FOR ANÆSTHETICS

The present position is that the I.A.C. by a small majority decided that anæsthetics should be included in the normal service, and that no special fees should be paid out of the central fund to the anæsthetist (frequently a partner or assistant) for this service. Some months ago as a result of pressure by the London panel committee the London insurance committee agreed to the principle that only 1*s.* should be allowed for any anæsthetic fee until regulations, which at present make some fee necessary, could be altered. The Ministry did not agree to this and await the opinion of the conference. It seems that in 2 areas of England and Wales the fee for a general anæsthetic is £2 2*s.*; in 9 areas it is £1 11*s.* 6*d.*; in 118 areas it is £1 1*s.*; and in 24 areas it is 10*s.* 6*d.* In none of the distribution schemes examined is provision for the payment of the anæsthetic fees absent, but in many areas panel committees refuse to grant applications for them.

LECTURES TO STUDENTS

Lectures to final-year students on health insurance practice are recommended by the I.A.C. as a means of improving the medical service. Little provision has been made for teaching the regulations in the medical schools of this country, the staff of which are often ignorant of the first principles of the Act. It is suggested that fees for these lectures should be paid for out of the interest on National Health Defence Trust capital. The conference last year suggested that these lectures should be given gratuitously by experienced men, but there is perhaps a limit to the amount of gratuitous work that can be demanded of practitioners even for one another. Lecture work to be effective can only be undertaken by men with experience of administrative work gained by service on panel and insurance committees. Such lectures should be paid for just as any other instruction on subjects within the medical curriculum by members of the staff of hospitals with medical schools attached.

THE MEDICAL CARD

There is apparently to be an alteration in the instructions printed on the medical card to prevent the present abuse by which insured persons moving into a new area wait until they are ill before changing their panel doctor for one living in the new neighbourhood. The wording is to be this :—

1. On receipt of this card if you have not chosen a doctor you should at once choose a doctor. You should fill up part A opposite and take the card to any insurance doctor you wish to choose.
2. If you remove permanently to a new address where you cannot get treatment from the doctor you have chosen, you can change to another doctor. You should at once fill up part B opposite and take the card to any insurance doctor you wish to choose.

Confidential Information

Staffordshire insurance committee has been considering a recommendation that practitioners on its list should be asked to furnish confidential information about the nature and duration of a patient's incapacity when requested to do so by approved societies in cases of difficulty. This was apparently agreed to and passed on to the medical benefit subcommittee for effective action (if any). The principle here involved seems to strike at the root of the normal relationship between doctor and patient. At the present time no doctor has the right to give information about a patient without that patient's consent to any third party, unless ordered to do so by a judge in court. This point has not, as far as we know, ever been raised in connexion with reports to regional medical officers where under regulations the doctor has to furnish information about a patient's condition to an officer of the Ministry. What would the position be if the patient refused his consent to such information being given? One of the present-day difficulties in certification is the absence of local control. In the old days every member was interested in his club, and if a member did not play the game the others soon saw to it that his incapacity was not worth while. In the national scheme there is no such protection for the funds of approved societies. Members and agents vie with one another to obtain benefits.

Panel Chemists

The terms of service for chemists under the N.H.I. Acts have been revised and the *Pharmaceutical Journal* for Sept. 3rd published some correspondence on the matter between the Ministry of Health and the National Pharmaceutical Union. The Ministry consider that Clause 4 (4) of the existing terms need no longer be retained as a safeguard against insurance prescriptions being asked for and issued merely for the sake of inducement in cash or kind held out by a chemist to insured persons. There has been no evidence of such practices since 1927. It is considered improbable that requests to doctors for medicine in excess of what is reasonably necessary will be made and granted for the sole purpose of securing increased dividends from coöperative societies. With regard to remuneration the negotiations are not quite finished. The Minister thinks that the excess of remuneration in 1930 and 1931 over the maximum amount guaranteed was more than can be justified if similar results are to be anticipated in the future. Some limitation is therefore necessary in the public interest, the first suggestion being to abandon continued experiments with rats that it is less likely than ergosterol or irradiation to produce a mineral imbalance that results in calcification of the organs. Hellwig has shown (*Arch. Pathol.*, April, 1931) that an excess of calcium induces goitre in rats. Perhaps some of the virtue of irradiated ergosterol in rickets lies in its activation of the thyroid as well as in its liberation of calcium from storage to be deposited in the bones. In a series of papers, preliminary abstracts of which have already appeared, we expect to furnish considerable information regarding the rôle of the balance between iodine and unsaturated hydrocarbons and fats in several deficiencies now classed as avitaminoses.

I am, Sir, yours faithfully,

F. E. CHIDESTER.

West Virginia University, Morgantown, West Virginia, August 29th, 1932.

MEDICAL NEWS

Royal Faculty of Physicians and Surgeons of Glasgow

At the close of the meeting on Sept. 5th, Mr. Walter Hurst, J.P., F.L.A., who had recently retired from the position of secretary to the Faculty, was presented by the President, Dr. R. Barclay Ness, on behalf of the Fellows, with a bureau and wallet with cheque, as a mark of appreciation of his work, extending over 25 years. Mr. Hurst took a keen interest in the success of the library, becoming familiar to a remarkable degree with its 120,000 volumes. As acting librarian he was able to help those whose work led them to dig deep in its literary treasures.

West London Hospital Post-Graduate College

The winter session begins on Oct. 13th, when Sir William Hale-White will give the opening address, at 3.30 P.M., on Bacilluria.

St. George's Hospital Medical School

The annual prize distribution will be held at 3.0 P.M. on Saturday, Oct. 1st, when Dr. E. Kaye Le Fleming will give an address on the General Practitioner: his Relationship to the State, the Public, and his Profession.

The annual dinner will be held on the same evening at the Hyde Park Hotel, at 7.15 for 7.45 P.M., when the chair will be taken by Sir Crisp English.

Westminster Hospital

A post-graduate course in general medicine and surgery will be held from Sept. 19th to Oct. 1st for men graduates only, under the auspices of the Fellowship of Medicine. Lectures or demonstrations are given every morning from 10.30 A.M. to 12.30 P.M., and two or three every afternoon between 2 and 4.30 P.M. Further particulars can be obtained from the secretary of the Fellowship of Medicine, 1, Wimpole-street, London, W.1.

Royal Sanitary Institute

A meeting will be held on Sept. 30th, in the Guildhall, Portsmouth, when discussions will take place on Municipal Engineering Works in Portsmouth, to be opened by Mr. Joseph Parkin; and on the Public Health Service: a Retrospect and a Forecast, to be opened by Dr. A. B. Williamson; Dr. Charles Porter presiding.

Medical Society of Individual Psychology

The first meeting of the session will be held, under the chairmanship of Prof. W. Langdon Brown, on Oct. 13th, at 11, Chandos-street, London, W.1, at 8.30 P.M. In the absence of Dr. Adler, Dr. Leonhard Seif, of Munich, will give an address in English on the Individual and the Community. This lecture is free to medical practitioners. On Oct. 14th Dr. Seif will address doctors and educationalists in Birmingham on Educational Aspects of Individual Psychology, and on Oct. 15th he will address the York Medical Society on Individual Psychology and Neurosis. On Oct. 17th, 19th, and 21st, Dr. Seif will lecture, under the auspices of the Individual Psychology Committee, at the School of Hygiene and Tropical Medicine, Keppel-street, London, W.C.1, at 8.30 P.M. Lecture I. will be on the Tendency to Freedom from Conflict in Life and Neurosis; Lecture II. on Resentment and Revolt; and Lecture III. on Individual Psychology and a Philosophy of Life. These lectures will be open to the public at a small charge.

Presentation to a Medical Man

On his retirement from the post of senior surgeon at the Blackburn and East Lancashire Royal Infirmary, after 25 years' service, Mr. R. Y. Aitken has been presented with his portrait in oils. Lord Moynihan made the presentation on Sept. 1st.

National Maternity Hospital, Dublin

The corner-stone of the new buildings was laid on Sept. 7th by Dr. Wall, Bishop of Thasos. The building will cost some £220,000, and the expense will be mainly defrayed from the results of the sweepstakes. Hitherto, the work of the hospital has been conducted in two rather unsuitable houses in Holles-street, but the committee has now succeeded in obtaining a site with a frontage on Merrion-square.

Increased Hospital Fees at Bangor

The committee of management of the Carnarvonshire and Anglesey Infirmary have increased the scale of charges for patients. Hitherto the fee has been 12*s.* 6*d.* per week, but it is now to stand at a minimum of £1 1*s.* per week with a subscriber's recommendation, and a minimum of £1 11*s.* 6*d.* without a recommendation. Out-patients will be charged 6*d.* for each attendance, with consideration for cases in which the charge cannot be met. These increases are necessitated by the higher cost of maintenance.

Anti-War Congress: International Medical Committee

This committee, consisting of doctors from Amsterdam, Berlin, London, Paris, Prague, Vienna, and Zurich, met during the congress held at Amsterdam from August 27th to 29th, and drafted an "appeal against war." The appeal sets out statistics showing the casualties in all countries during the war, and draws attention to the increased morbidity which it brought in its train. The committee propose to collect and spread information on the catastrophic effects of war on the public health.

Irish Hospital Sweepstakes

The audited accounts of the Irish Hospital Sweepstake on this year's Derby, which were issued recently, show that the total receipts were £4,128,485, and that the amount payable to the hospitals was £516,080. The prize fund was £2,804,552; stamp duty absorbed £258,030, and a similar amount was taken by the Ministry for local government. The expenses were £291,812.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED SEPT. 3RD, 1932

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 10 (last week 13); scarlet fever, 1332; diphtheria, 710; enteric fever, 89; acute pneumonia (primary or influenzal), 413; puerperal fever, 27; puerperal pyrexia, 126; cerebro-spinal fever, 24; acute poliomyelitis, 29; acute polio-encephalitis, 3; encephalitis lethargica, 3; continued fever, 3; dysentery, 85; ophthalmia neonatorum, 90. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Sept. 6th–7th was as follows: Small-pox, 20 (last week 24); scarlet fever, 1095; diphtheria, 1253; enteric fever, 15; measles, 389; whooping-cough, 426; puerperal fever, 21 (plus 6 babies); encephalitis lethargica, 230; poliomyelitis, 4; "other diseases," 116. At St. Margaret's Hospital there were 15 babies (plus 10 mothers) with ophthalmia neonatorum.

Deaths.—In 117 great towns, including London, there was no death from small-pox, 2 (0) from enteric fever, 11 (1) from measles, 2 (1) from scarlet fever, 19 (5) from whooping-cough, 24 (5) from diphtheria, 75 (18) from diarrhœa and enteritis under two years, and 13 (4) from influenza. The figures in parentheses are those for London itself.

The deaths from diarrhœa were 2 fewer than in the previous week: the highest figures being Liverpool, 11; Croydon and West Ham, each 4. The fatal cases of enteric fever occurred at Hastings and Grimsby. Three of the deaths from measles were reported from Liverpool. Diphtheria claimed 5 victims at Hull.

The number of stillbirths notified during the week was 252 (corresponding to a rate of 39 per 1000 total births), including 39 in London.

general use. Such treatment necessitates the undivided attention of the physician himself throughout its duration, and presupposes a docility on the part of the patient that cannot always be relied upon. Should accident or indiscipline produce a sudden alteration of current-strength, a burn or shock may occur. Wilde's thermal couch, dependent as it is upon low-pressure steam heating, and necessitating no pinioning of the patient in blankets, is free from these drawbacks, and its application can be safely left to a reliable nurse. With it a rise of mouth-temperature to 103° F. in 40 minutes is easily obtained, and 106° F. or higher may be reached after 60–90 minutes' treatment.

Such pyrexia is associated with profuse sweating but with no subjective feelings of distress and with no excessive rise of pulse-rate. Rates of 130 beats per minute are rare. In the case of the patient who is very ill, the treatment can be given by means of a portable apparatus, with equally satisfactory results. Should necessity arise, it can be terminated safely at any moment without risk of accidental damage. Such baths have been given without untoward effects in post-encephalitic parkinsonism and in early cases of G.P.I., and can be strongly recommended as a safe and simple method of applying artificial fever therapy.

I am, Sir, yours faithfully,
C. E. SUNDELL.

Queen Anne-street, Cavendish-square, W., Sept. 6th, 1932.

THE INNERVATION OF DENTINE

To the Editor of THE LANCET

SIR,—In an annotation in THE LANCET of August 20th (p. 408), on the important investigations of O. W. Tiegs into the innervation of the dentine, the following statement in regard to my work on this subject occurs :

> "He (D. Stewart) severed the inferior dental nerve in a cat on one side and later compared the pulps of the teeth with those of the opposite side. He found that histologically the fibres which Mummery had assumed to be nerve-fibres showed no difference in their staining reactions from those on the normal side ; he concluded that if they were nerve-fibres some change would be visible and that they must therefore be connective tissue fibres. But this work, significant though it be, does not take into account the possibility of some nerve-supply through the sympathetic fibres accompanying the blood-vessels."

Might I be allowed to say that in a later paper (*Jour. of Anatomy,* 1928, lxiii., 1–6) I was able to show that the fibres of Mummery were still present after both the inferior dental nerve and the peri-arterial nerve plexus around the inferior dental artery had been divided.

I am, Sir, yours faithfully,
D. STEWART.

Department of Anatomy, the University,
Manchester, Sept. 7th, 1932.

THE LONDON CLINIC AND NURSING HOME

To the Editor of THE LANCET

SIR,—Representing the medical group by whose initiative the London Clinic and Nursing Home came into existence, we feel that it is our duty to make some statement regarding its present situation. The public announcement of the appointment of a receiver and manager of the affairs of the company must suggest to our profession and to the public generally that the undertaking has come to a premature end. Were this the case it would indeed be a national disaster, for the Home sets a new standard in the medical and surgical treatment of private patients.

It is true that the company has under-estimated the amount of capital required for the building, its equipment, and its working, and that arrangements for additional capital will have to be made. The appointment of the receiver and manager is, however, not a destructive measure, but a protective measure, designed to enable the work of the Home to be carried on until arrangements for the additional capital can be made.

The medical group is affording the receiver all the advice and assistance which its members can give towards achieving efficient and economical working. They have no doubt of the ultimate success of the undertaking, and they are satisfied that during the period of financial reorganisation the reception of patients and the working of the Home will be carried on to the complete satisfaction of everyone concerned.

We are, Sir, yours faithfully,
(Signed) H. MORELAND MCCREA,
G. LENTHAL CHEATLE,
WALTER HOWARTH,
H. S. SOUTTAR

Sept. 12th, 1932. (on behalf of the Harley-street group).

IODINE IN AVITAMINOSIS

To the Editor of THE LANCET

SIR,—In your issue of May 14th (p. 1031) Mr. L. J. Harris, D.Sc., has made several suggestions regarding the mode of action of vitamin D which we believe can be further amplified by a report of our recent studies on leg-weakness in fowls. The results of our investigation, which will be more fully reported in *Endocrinology* (Chidester, Ashworth, Ashworth and Wiles), would seem to indicate that the iodine of cod-liver oil has long been an unconsidered factor in the prevention and treatment of rickets. Not only did our group find that thyroid extract prevented the appearance of leg-weakness, but a clinical report furnished us by a poultryman indicates that iodine administration prevented and cured leg-weakness appearing in a flock that presumably was receiving an adequate supply of cod-liver oil supplemented by fish meal.

Our experiment was incidental to a study of the influence of anterior pituitary extract intravenously injected. Previous workers had found that under such conditions, after a period of three or four weeks, the thyroids were depleted in iodine. Some of our experimental animals treated for more than four months developed leg-weakness and "slipped tendon."

It is our belief from a consideration of chemical analyses of the pituitary gland' that we produced a high-phosphorus low-calcium rickets, and that we also drew upon the stored iodine in the thyroid. It occurred to the writer that since the *parathyroids* apparently have such a profound influence on calcium deposition, it might be possible that they function as reservoirs of iodine. The long overlooked investigation of Gley indicates that such is the case. It is our belief that other analysts found the reservoirs empty, and hence reported a low iodine content.

It has been shown by several workers that both inorganic and organic iodine will prolong the lives of rats which have had an excess of irradiated ergosterol. The fact that the writer and associates (Chidester, Eaton, Speicher, Bourne, and Wiles) have been able to point out the great significance of iodine in three other vitamins, and that he has shown that the vitamin-A potency of cod-liver oil destroyed by oxygenation at a temperature of 120° C. for 24 hours can apparently be restored by adding iodine, naturally suggests a reason for the failure of oxidised cod-liver oil in the control of rickets, as described by Wagner and Wimberger (THE LANCET, 1924, ii., 55), and by other workers since that time.

While cod-liver oil itself may be given in too large quantities, we have considerable evidence from long-as a sheep was killed for the use of the family, I should be stripped and swathed up in the skin, warm as it was flayed from the carcass of the animal. In this Tartar-like habiliment, I well remember lying upon the floor of the little parlour in the farmhouse, while my grandfather, a venerable old man with white hair, used every excitement to make me try to crawl." Dr. Hutchison notes that he himself has been consulted as to the efficacy of this treatment of infantile paralysis. At 12 Scott was thought to have outgrown his strength, and at 14 suffered from a mysterious disease, associated with bleeding "in the lower bowels." We are left to speculate on its origin since, as Dr. Hutchison points out, Scott was then too old for polypus; too young for hæmorrhoids; ulcerative colitis is almost unknown at that age; and the history does not suggest typhoid fever. Scott recovered, and remained in robust health for ten years; he then had the first of the attacks of biliary colic, which recurred for a period of three years, and were ultimately cured following the exhibition of small doses of calomel, in which Scott had immense faith ever after. Six years later he had a solitary attack of renal colic, and two or three years afterwards, in 1826, developed rheumatism. Even before this time, in 1822, he had written to Terry of being annoyed by "a whoreson thickness of blood," which, on the basis of his subsequent history, Dr. Hutchison interprets as meaning the onset of high blood pressure. Scott dreaded a stroke, and in the same letter remarked, "Peveril will, I fear, smell of the apoplexy." In the years which followed he had seizures of increasing severity, and in 1832 an attack of "apoplexy combined with paralysis" occurred while he was in Germany. His surgeon had instructed a "confidential domestic, privately, in the use of the lancet," and immediate bleeding at the hands of this servant is said to have restored the signs of animation after his final stroke. At any rate, he was able to reach his home at Abbotsford, and it was several months before he died there on Sept. 21st, 1832.

EPIDEMIC DISEASE IN THE SUDAN

BILHARZIASIS is causing anxiety in the Blue Nile province. In his annual report as director of the Sudan medical service, Dr. O. F. H. Atkey tells us that in spite of a special effort to diminish the infection, which is endemic to certain blocks of the irrigated area, an increase in the number of children infected during the year has been recorded. The infection-rate among local natives has increased from 0·2 per cent. in 1930 to 0·75 per cent. in 1931. Snail destruction was not attempted throughout the irrigated area but was limited to canals in areas where the disease was endemic; these canals were treated with molluscicide in May and again in July, with the result that snails did not reappear until November, so that the new cases were presumably infected before May. The problem of prevention is complicated by the immigration of natives of western origin from Kordofan, Darfur, Wadai, and West Africa; in spite of a careful organisation to quarantine and treat such immigrants a considerable number of infected labourers find their way into the irrigated area. They are difficult to control, dirty, ignorant, irresponsive to propaganda, and disobedient to regulations, and are the main factor in the infection of canals. The best chance of sanitary improvement appears to lie in village planning and the establishment of public latrines. Up to date no effective action has been taken to provide latrine accommodation for the villages; their provision would not only prevent contamination of the canals, but would diminish the incidence of dysentery and other fly-borne diseases. "The present poverty of the people and the financial difficulties of the government," Dr. Atkey says, "combine to hinder the execution of these very necessary sanitary improvements." The infection-rate among women and girls is lower than among men, which is fortunate, as they are less ready to seek examination and treatment.

Relapsing fever has remained epidemic in the Blue Nile province and Khartoum province, and two outbreaks occurred in Darfur province which were attributed to immigrants from French territory. The case-mortality in the Blue Nile province was 13·4 per cent., as compared with 11·9 per cent. in 1930. Measures to prevent spread included passenger control in public vehicles; propaganda setting out the danger of associating with Western immigrants, and the value of early notification, bathing, shaving, and delousing of all clothes, bedsteads, and household goods. Outbreaks were dealt with by removing the sick to hospital, disinfection of their huts, and the shaving, bathing, delousing and medication of contacts. Contacts left in the field were given grey oil intramuscularly and marked on a finger-nail with a silver nitrate pencil. Of over 200 contacts so marked and left in the field, only one was subsequently admitted to hospital with relapsing fever, but others may have developed the disease who failed to report themselves as cases. A further 281 contacts were divided into four groups, those in three groups being treated respectively with tartar emetic, novarsenobillon, and grey oil; those in the fourth group, serving as controls, were not treated. Tartar emetic had to be dispensed with early as the injections were unpopular and the patients ran away. The results obtained indicated that antimony and arsenic prophylaxis increased the incidence of the disease among contacts, while grey oil reduced it, but the series was not sufficiently large for definite conclusions to be drawn.

The same three remedies were employed in the treatment of 492 cases of infection, which were divided into three groups for the purpose. Tartar emetic was again early discontinued owing to the high mortality under this treatment in 1930, and its unpopularity with the patients. The results indicated that grey oil was more effective than novarsenobillon in the treatment of relapsing fever, the case-mortality with novarsenobillon being 12·4 per cent., and with grey oil 11·9 per cent.

THE DEAVER MEMORIAL FUND

THE recent establishment by the Aid Association of the Philadelphia county medical society of a John B. Deaver perpetual memorial fund, the income from which is to be devoted to assisting needy physicians and their families, recalls the striking figure of one who at the time of his death a year ago was among the best known of American surgeons. Deaver came in touch with British surgeons at Oxford in 1904, when he read, before the British Medical Association, an important paper on hepatic drainage, which attracted considerable attention; and they reciprocated by regular visits to his clinic. Many went to witness his operative dexterity; even at an advanced age he was quick and spectacular. Many went to be entertained, for he had a gift of dramatic expression and his experience was exceptionally large. His literary output was considerable, with a pleasing style and a historical undercurrent which relieved the scientific exposition. His works on the breast, the prostate, and on appendicitis have become classics.

Born in 1855, near Buck, Pennsylvania, the son of a doctor, Deaver graduated in the University of Pennsylvania, and began private practice in Philadelphia. In 1884 he became demonstrator of anatomy, succeeded Joseph Leidy as assistant professor of applied anatomy seven years later, and in 1911 was appointed professor of surgery. From 1886 until his death on Sept. 25th, 1931, from severe secondary anæmia, he was attached as chief surgeon to the German Hospital at Philadelphia, since the war rechristened the Lankenau Hospital. His honours were numerous, and included the presidency of the American College of Surgeons in 1921. Though hundreds of active surgeons were his students, Deaver failed in one respect to achieve immortality, for his was a "one-man show"; he trained no disciples. The Deaver fund will, however, keep green the memory of a remarkable personality.

NOTES, COMMENTS, AND ABSTRACTS

THE PLACE OF THE MIDWIFE IN A NATIONAL MATERNITY SCHEME

FOLLOWING the issue of the final report of the departmental committee on maternal mortality and morbidity, the Midwives' Institute has put forward some suggestions designed to safeguard the position of midwives in a national maternity scheme. Any such scheme, in the view of the Institute, should cover the provision in every case of the services of a qualified midwife, chosen by the patient, to act either as a midwife, or, where the case is booked by a doctor, as a maternity nurse. The freedom of choice granted to the mother under the National Insurance Act should be maintained. When a midwife is available to act either as a midwife or as a maternity nurse at all confinements, the handywoman will take her rightful place as domestic assistant—i.e., home help. It is held that a scheme should provide for at least one medical antenatal and postnatal examination by the doctor, and should include cases of abortion. Sufficient hospital accommodation for abnormal cases should be included and should be reserved for such cases except when the home conditions are undesirable, or when the patient is prepared to pay full cost for hospital accommodation. It is submitted that any scheme should cover ambulance facilities for patients requiring to be removed to hospital, and telephone facilities for midwives, and that all midwives at present in practice should be included, if they so desire.

Other suggestions include the thorough instruction of midwives in the use of sedative and other drugs in obstetric practice as laid down by the rules of the Central Midwives' Board, no obstacles being placed by local authorities in the way of midwives using such drugs provided they understand their use and application. The need for more adequate attention by the midwife to important nursing duties than is possible under present conditions is emphasised; the departmental committee recommend in normal cases, morning and evening visits for the first three days, one visit thereafter up to and including the tenth day, and single visits on at least the twelfth and fourteenth days, where possible. Attention which includes such services might, it is held, justify an inclusive fee of three guineas per case, which could be considered the average standard. Attention is drawn to the financial disabilities under which midwives and especially those in independent practice are working to-day, and to the extent to which they suffer from bad debts or part payment. It is suggested that midwives in any district should meet and decide on a fair fee for the district and agree not to undercut each other, the local authority being approached to pay this agreed fee in necessitous cases.

The view is expressed that while consultant antenatal clinics are essential, the present increase of local antenatal clinics—where the doctor in attendance is neither a specialist nor the doctor the midwife could call in at the confinement—is unnecessary and expensive, both in money and in officers' time; necessary instruction in mothercraft, hygiene, and the making of clothes could be given to both expectant and nursing mothers at classes in connexion with existing infant welfare clinics. The claim of the midwife to representation on local committees, to compensation during suspension from work on grounds of infection or on admission of a booked patient to hospital, and to provision for old age is clearly set out. The document is a reasoned presentation of the midwife's aspirations, most of which will be recognised as legitimate, though the inclusive fee suggested will startle those who do not realise how much time must be devoted to maternity nursing if the mothers of the country are to have the best chance to regain and maintain their health and working capacity after childbirth.

In making these recommendations with regard to a National Maternity Scheme, it has been assumed that the necessary funds would be obtained mainly through insurance and in necessitous cases provided by the local authority.

DRUGS AND THE OTTAWA CONFERENCE

IT is understood that the British delegates pledged the British Government to place more and new duties on foreign imports of certain drugs, notably cod-liver oil, honey, and linseed. The proposed increase in the duty on honey is small, and the Empire could probably supply this country with all the honey it needs, so that an additional duty on foreign honey should not cause any marked increase in the price of honey. The suggested import duty on foreign linseed has evoked criticism, inasmuch as the bulk of this country's supply of linseed comes from South America, and it is said that India, the other source of supply, could not, for many years, supply all our requirements. What is being said in the markets about honey and linseed, however, is hardly audible above the noise that is being made about the proposed increase in the duty on foreign cod-liver oil. The proposal, so it is persistently but not officially reported, is for an additional duty of 1*s*. 4*d*. per gallon on imports of foreign, that is to say Norwegian cod-liver oil. This oil is already subject to a 10 per cent. ad valorem duty, and the effect of the increase would be to add about 40 per cent. to the wholesale price of practically all the cod-liver consumed in this country, thereby putting a strain on the insurance drug fund. Nearly all the Newfoundland cod-liver oil produced is, we understand, consumed in the United States of America, and this country depends on Norway as its main source of supply. That being so it would be a pity if the public had to pay much more for its cod-liver oil.

THE MEDICAL HISTORY OF SIR WALTER SCOTT

"A DOCTOR is like Ajax—give him light and he ma make battle with disease; but, no disparagement t the Esculapian art, they are bad guessers." Sir Walte Scott should have been a judge of doctors, for hi physical infirmities brought him into repeated contac with the profession which he thus temperatel criticised. Certainly he had to suffer, on occasion, fo the bad guesses of his physicians. Dr. Rober Hutchison, in a graphic account of the medical histor of Scott contributed to a recent symposium,[1] quotes letter written to Southey in 1819, when Scott ha been subjected to the contemporary treatment fo biliary colic: "If I had not the strength of a team o horses I could never have fought through it, an through the heavy fire of medical artillery, scarce les exhausting—for bleeding, blistering, calomel an ipecacuanha have gone on without intermission whil varying the agony of the spasms, laudanum becam necessary in the most liberal doses, though inconsisten with the general treatment." In another place h speaks of being "bled and blistered till I scarcely ha a pulse left." He seems to have been tolerant of th treatment meted out to him, however, and to hav submitted obediently, in spite of his contempt fo drugs and his shrewd opinion of certain medica caprices. Scott certainly suffered from a distressin variety of ailments. Dr. Hutchison takes us throug the whole gamut of them. At 18 months Scott fell victim to the attack of poliomyelitis which was to mak him lame for life; as a result of this he was subjecte to the remedies suggested by other "bad guessers besides those in the medical profession. "Amon the odd remedies," he says, "recurred to aid m lameness, someone had recommended that so ofte

ADDRESSES AND ORIGINAL ARTICLES

ERRORS IN DIAGNOSIS*

BY ADOLPHE ABRAHAMS, O.B.E., M.D. CAMB., F.R.C.P. LOND.

PHYSICIAN TO OUT-PATIENTS, WESTMINSTER HOSPITAL; PHYSICIAN, THE HAMPSTEAD GENERAL HOSPITAL

A LECTURER who chooses this not unfamiliar subject is inevitably upon the horns of a dilemma. On the one hand it demands almost superhuman courage to select material from his own humiliating experiences, and with the best of intentions it is only human nature to develop amblyopia and deafness in respect to one's own deficiences. On the other hand, the more comfortable method of enumerating the mistakes of others carries with it an unworthy sense of triumphant condemnation as well as the implication of personal infallibility.

Nearly twenty years ago I composed a paper on the material derived from a series of lectures, 34 in number, delivered by distinguished consultants and specialists, each of whom dealt with the common mistakes which he had encountered in his own specialty, almost invariably, I may add, at the hands of somebody else. At that time I analysed and synthesised the impressions acquired from these lectures, and produced what I felt justified in calling "Common Errors in Diagnosis." But it is not a good title. A common error in one man's opinion is a most uncommon one in another's. The criterion of difficulty is an arbitrary elastic one, and it is better to avoid any such qualification and consider the subject as a whole.

THE CAUSES OF MISTAKES

In the classification of the causes of mistakes in diagnosis there is scope for ingenuity and resource. You may differentiate mistakes as pardonable and unpardonable. Or you may classify them under the two headings—things which we miss altogether, and things which we mistake for others. Or as negative errors—i.e., overlooking signs which are present—and positive errors, the discovery of mares' nests, exaggeration of the negligible, or inability to recognise the limits of the normal. Or, again, as mistakes arising from the incomplete observation of facts, and those which are conclusions drawn from inadequate evidence. These classifications overlap, and are to some extent tautologous; but before concluding this enumeration of possible classifications one is reminded of the perpetrations traceable to such inborn errors of character as apathy, indifference, carelessness, and conceit. Osler said that the physician, like the Christian, has three great foes: ignorance, which is sin; apathy, which is the world; and vice, which is the devil. Vice will comprise nearly all causes of serious mistakes in diagnosis, if under vice we include failing to take sufficient care.

The first possible cause of faulty diagnosis is that which may occur before the patient is seen, when judgment is unalterably warped by some prepossession or inculcated prejudice. The method of avoidance is obvious, if not always easy. Another cause may be as summarily dismissed: mistakes which arise from bad manners, tactlessness, or mismanagement. Here there underlies a fundamental mistake—that the doctor has mistaken his vocation. Most mistakes in the diagnosis of gastro-intestinal diseases and disorders are due to inadequate or imperfect handling of the patient during the preliminary interrogation. The anamnesis may be invaluable; it is often indispensable to a correct diagnosis; but in certain instances the rôle of cross-examination is negligible. In the attempt to obtain corroborative evidence from a patient it requires some tact and much patience to decide between useful information and garrulous imbecility. The manner of the interrogator makes all the difference in the world to the nervous or suspicious patient, who feels that his sentiments are being palpated, and his conscience auscultated long before the physical examination begins.

In this connexion it may be added how great a mistake it is to say too much too soon. Once the diagnosis is out of the doctor's mouth he is certain to be overwhelmed with questions about the probable course and duration of the illness. And until his diagnosis is as reasonably certain as any diagnosis can be certain, it is far better to refrain from any unqualified opinion. Even to name a disease or condition may be fraught with disaster. Armed with this, the patient or a relative proceeds to look it up, and so learns all the horrors which may be expected in the way of possible complications and termination. Some doctors take a pride in dispensing all available information to their patients on the principle that they have a right to know, quite independently of the patients' ability to understand the technicalities in their proper proportions, or of their own ability to describe lucidly and simply. Others go to the other extreme of pontifical profundity clothed in absolute silence. Doubtless there is, as usual, a happy mean. I am not at all sure that the over-cautious man who acquires a reputation as an alarmist is not criticised for his mistakes more sharply than his cheery breezy opposite, who seems congenitally incapable of ever imagining the existence of a grave disease. After all what, in the majority of cases, the patient and his friends are concerned about is not the academic beauties of differential diagnosis, but whether and how soon he is going to recover. They are not in the least interested in the doctor's impressions of structural changes in the organs affected, and they cannot possibly share his solicitude. They want his opinion upon the possibility of repairing the damaged machine, or, alternatively, upon the prospects of its continuing to run in its irreparable state. The uncertainty in regard to such questions makes a cautious answer imperative. For diagnosis is but the balance of probabilities, and often we are seduced into making a diagnosis before the pendulum has stopped swinging. A revision upon more mature consideration and further investigation may completely alter the prognosis, a volte-face which will never be understood and rarely forgiven. Occasionally, of course, the physician with a wrong diagnosis arrives at a correct prognosis or, as it is popularly said, he gains on the swings what he loses on the roundabouts; but such good fortune is too rare to be counted upon.

Mistakes due to Ignorance

To turn now to the classification of the causes of errors of diagnosis on clinical grounds, first there is ignorance. Ignorance is always relative. For purposes of discussion I would distinguish gross, moderate, and condonable ignorance. Gross ignorance is naturally very rare, but occasionally one encounters examples which leave a sense of wonder that the

* A post-graduate lecture delivered at Westminster Hospital on Sept. 20th.

THE EFFICIENT HOSPITAL PHARMACOPŒIA

AT Aberdeen, on Sept. 13th, Mr. Herbert Skinner addressed the British Pharmaceutical Conference on the Hospital Pharmaceutical Service. It was, he said, the first time a practising pharmaceutist in hospital service had been chosen chairman of the conference. Although, he went on, the compounding of medicaments was neither the beginning nor the end of hospital pharmacy, yet the pharmaceutist required to be skilled in constructing formulæ to produce the best therapeutic effects, often from somewhat scanty information. The exigencies of the medical service make it a desirable thing, in this respect, that he should be of material assistance to the physician and surgeon. If the tendency to bank on known, admitted, and approved compounds was too marked, it gave opportunity to the novelty merchant to put across his elegant variations. Thus, quietly, for years hospital pharmacists had practised blending hypnotics with antipyretics to accentuate the hypnotic effect, and left it to external clinics to exploit the idea as a novelty. Their formulæ for ointments of known dermatological value were often tried out in foreign clinics, and returned to them disguised under a meaningless branded name. There was a real danger of getting into a rut, which the comparatively safe economic position in the public service had a tendency to encourage. "Pharmaceutically speaking," he said, "we lose the essence of things if we forget that the price of progress is eternal vigilance. The production of an efficient hospital pharmacopœia is our job."

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Sept. 19th, to SATURDAY, Sept. 24th.—WESTMINSTER HOSPITAL. Post-graduate course in general medicine and surgery. All day. Open to men graduates only.—INFANTS HOSPITAL, Vincent-square, S.W. Post-graduate course in diseases of Infants. Afternoons.—ROYAL EYE HOSPITAL, St. George's Circus, S.E. Course [illegible] noon. Clinical [illegible] HOSPITAL, Monk's O[illegible] Tues. and Fri. at 11 [illegible] logical Medicine. (Courses are open only to Members of the Fellowship.)

CENTRAL LONDON NOSE, THROAT, AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, Sept. 23rd.—4 P.M. Mr. W. A. Mill: Earache in the Normal Ear.

Vacancies

For further information refer to the advertisement columns

All Saints' Hospital, Austral-street, West-square, S.E.—Hon Anæsthetist.

Archway Hospital, Archway-road, Highgate, N.—Asst. M.O. £350.

Bangor, Caernarvonshire and Anglesey Infirmary.—Jun. H.S. £100.

Barnsley, Beckett Hospital and Dispensary.—Cas. O. £250.

Bath, Royal United Hospital.—H.P. At rate of £175.

Bethnal Green Hospital, Cambridge-road, E.—Two Asst. M.O.'s. £350.

Birmingham, St. Chad's Hospital.—Res. M.O. £100.

Cardiff Royal Infirmary.—Two H.S.'s to Special Depts. Each at rate of £50.

Central London Ophthalmic Hospital, Judd-street, W.C.—Asst. Surgeon.

Cheltenham General and Eye Hospital.—H.S. £300.

Chester, East Lancashire Tuberculosis Colony, Barrowmore Hall, Gt. Barrow.—Asst. M.O. At rate of £275. Also H.P. At rate of £100.

Colchester, Essex County Hospital.—Asst. H.S. £120.

Colchester, Royal Eastern Counties' Institution, &c.—Res. Asst. M.O. £350.

Elizabeth Garrett Anderson Hospital, Euston-road, N.W.—Asst. Radiologist for X Ray Dept. £100.

Evelina Hospital for Sick Children, Southwark, S.E.—H.P. At rate of £120.

Fareham, Hants, Knowle Mental Hospital.—Second Asst. M.O. £550.

Gloucester, Gloucestershire Royal Infirmary, &c.—H.S. At rate of £150.

Halifax [illegible] £150.

Hertford [illegible] t rate of £200.

Ilford, E [illegible] Cas. H.S. £100.

Ipswich, [illegible] *Hospital.*—H.S. £120.

Lambeth [illegible] —Asst. M.O. £350.

Leaming [illegible] *Hospital.*—Res. H.S. and H.P. Each £165.

Liverpool, Alder Hey Children's Hospital.—Res. Asst. M.O. £200.

Liverpool, St. Paul's Eye Hospital, Oldhall-street.—H.S. At rate of £145.

Liverpool, Stanley Hospital.—H.S. At rate of £100.

London Lock Hospital, 91, Dean-street, W.—Surg. Reg. £100.

Maternity Nursing Association, 63, Myddelton-square, E.C.—M.O. 1½ gns. per session.

Mile End Hospital, Bancroft-road, E.—Asst. M.O. £350.

Miller General Hospital, Greenwich-road, S.E.—Hon. Surgeon to Nose, Throat, and Ear Dept.

[illegible] Part-time Surg. Reg. £250.

[illegible] *for Sick Children.*—H.P. Sen. [illegible] ate of £100.

Oswestry, Shropshire Orthopædic Hospital, &c.—H.S. At rate of £200.

Princess Beatrice Hospital, Richmond-road, Earl's Court, S.W. Res. M.O. At rate of £100.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Res. M.O. for Isolation Hospital, Hammersmith, W. £200.

Queen's Hospital for Children, Hackney-road, E.—Ophthalmic Surgeon.

Royal Eye Hospital, St. George's-circ[illegible] *S.E.*—Eighteen Clin. Assts. Pathologist, £100. Twelve [illegible] Dept. Each £80. Also Nine [illegible] Each £50.

Royal Free Hospital, Gray's Inn-road, W.C.—Res. Cas. O. At rate of £150.

Royal Northern Hospital, Holloway, N.—H.S. At rate of £70.

St. Albans and Mid-Herts Hospital and Dispensary, Church-crescent.—Res. H.S. £150.

St. Helens County Borough.—Asst. M.O.H. £600.

St. Helens Hospital.—H.S. £200.

St. Leonard's Hospital, Hoxton-street, N.—H.P. At rate of £80.

St. Mary Islington Hospital, Highgate Hill, N.—Asst. M.O. £250.

St. Pancras Hospital, Pancras-road, N.W.—Asst. M.O. £250.

Salford [illegible] Res. H.S.'s to Special Depts. Each [illegible]

Sheffield [illegible] Aural and Ophth. H.S. At rate [illegible]

South London Hospital for Women, Clapham-common, S.W.—H.P. and H.S. Each at rate of £100.

Stockport Infirmary.—H.P. £150.

Walsall General Hospital.—H.P. and Res. Asst. Pathologist. At rate of £150.

West Bromwich and District General Hospital.—Hon. Gynæcologist and Hon. Physician. Also Cas. H.S. £200.

West London Hos[illegible] —Hon. Anæsthetist. Also [illegible]

Winchester, Royal [illegible] -H.P. At rate of £125.

[illegible] *oss Hospital.*—Res. Asst. M.O. £200.

[illegible] *nary.*—Pathologist. £400.

[illegible] M.O. £175.

The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Glyn Ceiriog (Denbigh).

Births, Marriages, and Deaths

BIRTHS

RUDD.—On Sept. 7th, at a nursing home, the wife of Dr. A. S. Rudd, Park-road, Crouch End, N., of a son.

WILLIAMS.—On August 27th, the wife of H. Keith Williams, *M.C.*, M.B., B.S. Lond., Attwood House, Basingstoke, of a daughter.

WOODHOUSE.—On August 29th, at South-street, Romford, the wife of R. A. Woodhouse, M.D. Camb., of a son.

MARRIAGES

DUNCAN—FINCH.—On Saturday, Sept. 10th, at St. Thomas's Church, Purston, John Duncan, M.B., Ch.B., elder son of Mr. and Mrs. Duncan, of Roundhay, Leeds, to Helen Maud, younger daughter of Dr. W. S. and Mrs. Finch, Purston, Pontefract, Yorks.

DEATHS

DINGLE.—On Sept. 7th, at "Strathmore," Ilfracombe, William Alfred Dingle, M.D., T.D., formerly of Finsbury-square, E.C., aged 82.

HOPKINS.—On Sept. 7th, at a nursing home, John Hopkins, F.R.C.S.

STEVENSON.—On Sept. 12th, at New Barnet, Herts, Thomas Henry Craig Stevenson, C.B.E., M.D.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

he upper end of the rectum may in itself give rise o very few symptoms, but by pressure cause hæmorhoids. Recently I correctly diagnosed gall-stones n a woman with characteristic symptoms, but overlooked a carcinoma of the stomach discovered at operation for the other condition.

Failure to Think Anatomically

It was C. B. Lockwood, always to be gratefully remembered by his pupils as a remarkable clinical teacher, who perpetually emphasised the importance of thinking anatomically. I recall the simplicity, yet the almost uncanny skill, with which the source for dysphagia was isolated in an inflamed gland beneath the sternomastoid muscle as he proceeded down the route of deglutition from the tongue itself. Reflex phenomena—e.g., otalgia from carious teeth, cough or hiccup of aural origin, abdominal pain in a child due to spinal caries, or in an adult to cardiac disease, these are a few obvious and commonplace examples of applied anatomy, examples which might be indefinitely multiplied. A recent experience is worth recording. A girl of 17 was exhibited to a number of experienced physicians and surgeons, all of whom diagnosed bilateral parotid tumour, and discoursed exhaustively on the possible causes of such tumours, until a final contributor to the discussion pointed out that anatomically considered the swellings could not possibly be of the parotid glands, that an entirely different explanation must therefore be forthcoming, and that the tumours were in fact lipomata.

Incomplete Examination

It is no exaggeration to protest that nearly all avoidable mistakes can be included in this category. How many really important mistakes would be avoided if we made it an invariable rule to examine at least perfunctorily from head to foot, including urinalysis and the use of the ophthalmoscope, the clinical thermometer, the hæmoglobinometer, and the sphygmomanometer? The range of examination may be indefinitely extended, but I suggest this as a kind of irreducible minimum which would act as a net, coarse enough to be of practical application, yet fine enough to retain the greater bulk of morbid conditions generally encountered.

Many grave errors result from simple neglect to take the temperature, and, one may add, to take it properly. Headache and seediness exact much more respect if fever is found to be present. Pain in the side may be neuralgia or muscular rheumatism or indigestion or some other trifle, but accompanied by a raised temperature at once suggests the possibility of pleurisy, splenic infarct, or other grave condition. Whilst the association of pyrexia with abdominal pain at once labels the complaint as serious, demanding an order for bed and further searching examination.

The thermometer may supply a warning that the course of an illness which has been correctly diagnosed is not proceeding normally—e.g., in pneumonia the development of an empyema; in rheumatic fever the onset of pericarditis or endocarditis. Or it may indicate the development of some complication in an illness in which the usual course is apyrexial.

What are the causes of incomplete examination? First of all, because there is no time, owing to extreme pressure of work, for more than what a photographer would term a snapshot diagnosis. Utterly unpardonable is the diagnosis made upon the patient's symptomatic description without examining the part. How many times has "rheumatism" been let out of a swelling with a scalpel? In my own experience I have seen sarcoma, osteomyelitis, popliteal aneurysm, and acute epiphysitis masquerading under this popular ready-made diagnosis.

Whatever the complaint, and however preposterous the symptomatology, the region complained of must at least be looked at and undergo at least a cursory examination secundum artem. Neglect of this fundamental can admit of no defence. During the war I saw two R.A.M.C. officers suffer the most severe reprimand for stigmatising a man as a malingerer, and neglecting to examine him for his chronic backache. He had a huge aortic aneurysm visible at a distance of several yards. Undue reliance upon a symptom or physical sign often encourages neglect of further examination. I may instance a patient treated for 12 months for "cystitis." The abdomen had never been examined or a large tumour infiltrating the bladder would have been discovered. As another example œdema of the feet in a man attributed to anæmia. He had anæmia, it is true; in any case a most unsatisfactory explanation of œdema, but the anæmia was due to secondary malignant glands pressing upon the inferior vena cava, the primary source of which was a large painless tumour of the testis. The coexistence of glycosuria with a wasted leg was diagnosed as diabetic neuritis and protracted anti-diabetic treatment was ordered. It had not been observed, however, that the knee-jerk was brisk, and that the hip was fixed. It was, in fact, a case of old tuberculous arthritis, and the glycosuria was a transient accompaniment of hyperthyroidism.

Alternatively it sometimes happens that in a very obscure case there is an undue tendency to presume the importance of some positive discovery simply because one is happy to find anything positive. In this respect one thinks of the ubiquitous Wassermann reaction or of a bacilluria which, though merely a saphrophytic association, distracts attention from the deep-seated more elusive lesion which is really responsible for the illness.

ACCEPTANCE OF AUTHORITY

Incomplete examination may arise from a blind acceptance of somebody else's authority. Here one treads upon very thin ice. Naturally, to appear to cast doubt upon the value of a colleague's observations by repeating his examinations is liable to give offence, yet the unquestioned acceptance of his results may lead to disaster.

Inexplicable high or low blood pressures lose their mystery when it is evident that the apparatus must have been inaccurate. Absent tendon-jerks which have puzzled one observer and confuse the issue are found to be really brisk if a patellar hammer be employed. On one never-to-be-forgotten occasion I refrained from a digital examination of the rectum because I had been assured that a very eminent predecessor had only 24 hours previously passed this as normal. On the following day a third less confiding examiner humiliated me by finding an obvious growth within easy access.

In the matter of physical signs, however great the authority of previous examiners, one's own individual judgment should be formed. I feel that none of us ought ever to be offended at the scrutiny of our observations. If we are right we shall be confirmed; if we are wrong it is best to be corrected; and if it is a matter of interpretation difference of opinion is legitimate.

portals of qualification could ever have been passed. I was once asked to see a condition of "acute metritis" four days after delivery, when the large pyriform swelling in the abdomen was the bladder containing half a gallon of urine. And to forget that wax in the ears is a common cause of deafness might be included in this category.

Ignorance of the fundamentals, though not so extreme as to be labelled gross ignorance, is the diagnosis of articular rheumatism before the age of two, when scurvy or acute epiphysitis is overlooked. Ignorance of the symptoms and physical signs of early phthisis because apical dullness is not present. The popular identification of certain substances in the motions of infants as food residues, which are really insoluble soaps. Ignorance in the proper use of drugs, especially of those with a specific action—salicylates in rheumatism, quinine in malaria, urotropin in bacilluria, digitalis in auricular fibrillation; these are examples of drugs with a diagnostic value. One encounters instances when a diagnosis has been abandoned because the specific action of the drug has not been obtained, although quite inadequate doses have been administered.

As condonable ignorance I would refer to the want of acquaintance with comparatively rare diseases. Occasionally the tyro makes a brilliant diagnosis through his very ignorance of how rare such a condition is. In this category I am particularly thinking of what we term new diseases, with the somewhat disquieting reflection that they must hitherto have been there all the time and overlooked. Consider, for example, the fever due to the *Brucella abortus*; the disease, psittacosis; the syndrome known under the name of Plummer-Vinson; and the microcytic anæmias of women which Witts has made so familiar. I remember some 18 years ago being introduced to what the demonstrator described as the rarest disease in the world—congenital familial steatorrhœa. On the very next afternoon the first patient to enter my room was an example of this disease, of which until the previous day I had never heard. According to one's opportunity to keep au courant with medical literature, the failure to identify relatively rare diseases is more or less condonable. But on the whole we do not worry over such failures; rather the opposite is to be deprecated, the mistake of too frequently expecting or identifying the rare and unusual.

Inexperience or Faulty Judgment

These are only with some artificiality separated from the preceding. Perhaps as an instance of a distinction relating to inexperience one may cite mistakes arising from inability to judge cardiac and, a fortiori, pulmonary sounds at their proper value when the limits of the normal can be estimated only after prolonged experience. Most of us have seen instances of functional albuminuria treated for years as examples of nephritis. A reduplicated first sound is not always distinguished from a presystolic murmur, and unnecessary hardship in the way of restricting activities not avoided. An obstinate case of rheumatism localised to one joint may be treated as tuberculosis; a child who is merely deaf may be condemned as mentally defective.

I have already mentioned phthisis as an example of a disease which in its early stages may be overlooked through ignorance; somewhat similar mistakes attributable to inexperience may be multiplied in every branch of medicine. The least experienced can diagnose a case of disseminated sclerosis when all the classical signs and symptoms are so obvious that they can be recognised with a telescope from the end of a road. Trivial early signs quite insignificant to the novice will be identified by the man of experience. Varying degrees of experience with instruments of precision put us all into a number of grades and classes as the eye and ear are trained, as at one time I suppose the sense of smell was also used. Judgment in assessing the value of pathological and other evidence which is to be employed in establishing a diagnosis naturally demands profound experience of pathologists, their work, and the relation of their work to clinical medicine.

On the social side there is no limit to the judgment of human nature. The young doctor has to learn that pregnancy can never be excluded on a priori grounds of spinsterhood, separation, widowhood, social position, or the assertion that it is impossible. To overlook or wrongly to diagnose pregnancy i one of the mistakes which will never be forgiven.

Mistakes due to Obsession

It is no impertinence to submit that not even th most experienced can be entirely immune to thi cause of error. Whatever one's intentions, it is ofte impossible to avoid concentrating the attention upo a certain hypothesis and unconsciously distortin the circumstances to agree with it, whilst blindin oneself to other conditions which might have ensure revision of judgment. I once saw a class of l experienced general practitioners examining a swellin in the right iliac fossa. The demonstrator ha skilfully directed their attention to abdomina conditions, and restricted himself to their differentia diagnosis. As a consequence not one thought o examining the spine, which would at once hav revealed caries as a source of the swelling, a tuberculou abscess.

The specialist is naturally prone to dwell upon th particular features of his specialty, and only a goo general training can combat a perpetual tendenc towards this obsession and preserve a proper sens of values. Dr. Robert Hutchison quotes the exampl of a chest specialist unable to consider the usua causes of an ischio-rectal abscess because he had onc heard of or seen an empyema pointing in that situa tion! A dry throat considered as a local lesion ma be overlooked as an accompaniment of diabetes, laryngeal spasm as a manifestation of locomoto ataxia, a stuffy nose as an indication for thyroi extract.

An almost inevitable cause of obsession arises fro the traditional expectation of encountering a secon example of some relatively rare condition shortl after one has appeared, and this is associated wit the error of diagnosing on a general superfici resemblance to something recently seen. Apparentl no amount of persuasion to the contrary will destro the inclination to rely upon a supposed tendenc of rarities to run in couples, trios, or even group And although teachers of medicine are perpetuall pointing out the folly embodied in the second fallac no amount of experience appears to confer immunit After a particularly brilliant diagnosis, the observ is frequently incapable of forgetting his succes and, during this period of incapacity, judgment warped and the diagnostic field is thrown out focus.

As a rather special form of obsession there is th overlooking of the more serious of two simultaneou conditions. It is always advanced as a good gener principle to include all symptoms so far as possib under one cause, but this is not absolute. The le serious condition which is first observed natural attracts chief attention—e.g., malignant disease the upper end of the rectum may in itself give rise to very few symptoms, but by pressure cause hæmorrhoids. Recently I correctly diagnosed gall-stones in a woman with characteristic symptoms, but overlooked a carcinoma of the stomach discovered at operation for the other condition.

Failure to Think Anatomically

It was C. B. Lockwood, always to be gratefully remembered by his pupils as a remarkable clinical teacher, who perpetually emphasised the importance of thinking anatomically. I recall the simplicity, yet the almost uncanny skill, with which the source for dysphagia was isolated in an inflamed gland beneath the sternomastoid muscle as he proceeded down the route of deglutition from the tongue itself. Reflex phenomena—e.g., otalgia from carious teeth, cough or hiccup of aural origin, abdominal pain in a child due to spinal caries, or in an adult to cardiac disease, these are a few obvious and commonplace examples of applied anatomy, examples which might be indefinitely multiplied. A recent experience is worth recording. A girl of 17 was exhibited to a number of experienced physicians and surgeons, all of whom diagnosed bilateral parotid tumour, and discoursed exhaustively on the possible causes of such tumours, until a final contributor to the discussion pointed out that anatomically considered the swellings could not possibly be of the parotid glands, that an entirely different explanation must therefore be forthcoming, and that the tumours were in fact lipomata.

Incomplete Examination

It is no exaggeration to protest that nearly all avoidable mistakes can be included in this category. How many really important mistakes would be avoided if we made it an invariable rule to examine at least perfunctorily from head to foot, including urinalysis and the use of the ophthalmoscope, the clinical thermometer, the hæmoglobinometer, and the sphygmomanometer? The range of examination may be indefinitely extended, but I suggest this as a kind of irreducible minimum which would act as a net, coarse enough to be of practical application, yet fine enough to retain the greater bulk of morbid conditions generally encountered.

Many grave errors result from simple neglect to take the temperature, and, one may add, to take it properly. Headache and seediness exact much more respect if fever is found to be present. Pain in the side may be neuralgia or muscular rheumatism or indigestion or some other trifle, but accompanied by a raised temperature at once suggests the possibility of pleurisy, splenic infarct, or other grave condition. Whilst the association of pyrexia with abdominal pain at once labels the complaint as serious, demanding an order for bed and further searching examination.

The thermometer may supply a warning that the course of an illness which has been correctly diagnosed is not proceeding normally—e.g., in pneumonia the development of an empyema; in rheumatic fever the onset of pericarditis or endocarditis. Or it may indicate the development of some complication in an illness in which the usual course is apyrexial.

What are the causes of incomplete examination? First of all, because there is no time, owing to extreme pressure of work, for more than what a photographer would term a snapshot diagnosis. Utterly unpardonable is the diagnosis made upon the patient's symptomatic description without examining the part. How many times has "rheumatism" been let out of a swelling with a scalpel? In my own experience I have seen sarcoma, osteomyelitis, popliteal aneurysm, and acute epiphysitis masquerading under this popular ready-made diagnosis.

Whatever the complaint, and however preposterous the symptomatology, the region complained of must at least be looked at and undergo at least a cursory examination secundum artem. Neglect of this fundamental can admit of no defence. During the war I saw two R.A.M.C. officers suffer the most severe reprimand for stigmatising a man as a malingerer, and neglecting to examine him for his chronic backache. He had a huge aortic aneurysm visible at a distance of several yards. Undue reliance upon a symptom or physical sign often encourages neglect of further examination. I may instance a patient treated for 12 months for "cystitis." The abdomen had never been examined or a large tumour infiltrating the bladder would have been discovered. As another example œdema of the feet in a man attributed to anæmia. He had anæmia, it is true; in any case a most unsatisfactory explanation of œdema, but the anæmia was due to secondary malignant glands pressing upon the inferior vena cava, the primary source of which was a large painless tumour of the testis. The coexistence of glycosuria with a wasted leg was diagnosed as diabetic neuritis and protracted anti-diabetic treatment was ordered. It had not been observed, however, that the knee-jerk was brisk, and that the hip was fixed. It was, in fact, a case of old tuberculous arthritis, and the glycosuria was a transient accompaniment of hyperthyroidism.

Alternatively it sometimes happens that in a very obscure case there is an undue tendency to presume the importance of some positive discovery simply because one is happy to find anything positive. In this respect one thinks of the ubiquitous Wassermann reaction or of a bacilluria which, though merely a saphrophytic association, distracts attention from the deep-seated more elusive lesion which is really responsible for the illness.

ACCEPTANCE OF AUTHORITY

Incomplete examination may arise from a blind acceptance of somebody else's authority. Here one treads upon very thin ice. Naturally, to appear to cast doubt upon the value of a colleague's observations by repeating his examinations is liable to give offence, yet the unquestioned acceptance of his results may lead to disaster.

Inexplicable high or low blood pressures lose their mystery when it is evident that the apparatus must have been inaccurate. Absent tendon-jerks which have puzzled one observer and confuse the issue are found to be really brisk if a patellar hammer be employed. On one never-to-be-forgotten occasion I refrained from a digital examination of the rectum because I had been assured that a very eminent predecessor had only 24 hours previously passed this as normal. On the following day a third less confiding examiner humiliated me by finding an obvious growth within easy access.

In the matter of physical signs, however great the authority of previous examiners, one's own individual judgment should be formed. I feel that none of us ought ever to be offended at the scrutiny of our observations. If we are right we shall be confirmed; if we are wrong it is best to be corrected; and if it is a matter of interpretation difference of opinion is legitimate.

SUBORDINATION OF CLINICAL TO EXTRA CLINICAL METHODS

The invasion of pathology and radiology into the field of investigation is, of course, an infinitely progressive one. And it is perhaps inevitable, though unfortunate, that clinicians tend more and more to seek short cuts in diagnosis by invoking the assistance of one or other or both of these colleagues. Admittedly there are occasions when an absolute diagnosis is rapidly and unequivocably obtained by some pathological or radiological investigation. But the timid clinician is sometimes inclined too readily to distrust his own acumen and yield to the dogmatic pronouncements of film or slide which do not consort with his clinical impressions.

It is well to refer to the sources of error in such an attitude. In the first place, although the explanation cannot apply in many instances it is by no means unknown for the wrong radiogram or pathological report to be submitted, and no amount of precaution can ever entirely eliminate this possibility. Clerical errors may be responsible. I have seen the omission of a digit on two occasions with overwhelming consequence—a blood-urea examination, for example, returned as 24 mg. per cent. when 240 was intended. But putting these avoidable sources of error on one side, it must be admitted that pathologists and radiologists vary considerably both in skill of performance and of interpretation. I have seen the most serious consequences follow the return of a positive Wassermann reaction accepted at its face value, when other pathologists unhesitatingly returned a negative. Misleading reports as to infections, total and differential leucocyte counts, and agglutination tests have led to weeks of weary investigation resulting from the unquestioned acceptance of these results as excluding or indicating certain diseases.

Pathological results are often invaluable, they are generally valuable, they are sometimes embarrassing. They are to be used in their proper relation to diagnosis, and it is quite wrong to accept the ipse dixit of any pathologist, either as a substitute for clinical examination or as a negation of any clinical opinion with which it may not accord. And as regards the radiologist, improving technique shows how many mistakes have occurred in the past from faulty conclusions dependent on the angle of the rays or other technical causes, from the misinterpretation of the nature of an opaque body, or when the elaboration of special methods such as Graham's test, reveals errors which are not at first realised. To accept the dogmatic pronouncement that since there is no X ray evidence of cholecystitis or cancer of the stomach these conditions must be excluded is a dangerous source of error which most clinicians have had cause to deplore.

LAZINESS

As an easily avoidable cause of insufficient examination laziness must unhappily be included. Laziness has led to the employment of labour-saving apparatus. There is a preposterous instrument which promises that the chest may be auscultated without the preliminary precaution of removing the patient's clothes. It may possibly spare the physician the occasional disadvantage of the unattractive aroma of disrobing out-patient humanity. And it may easily lead to the diagnosis of all sorts of supposed pulmonary and pleural sounds which result from the creaking of a pair of leather braces. Furthermore, one can hardly encourage the handicap of endeavouring to hear slight modifications of the breath sounds
through a coat, waistcoat, shirt, three vests, and a
chest protector. It is just as well too to examine
the whole of the chest, and not restrict oneself to an
obviously abnormal part. I have twice seen early
tubercle of the right apex diagnosed because the note
at this apex was flatter and the breath sounds were
louder. But a pleural effusion at the left base had
been overlooked which had compressed the left lung
and caused hyper-resonance of the left apex. Thu
the not uncommon mistake of not recognising th
abnormal side of the chest might have been avoide
by complete examination.

Examination of the whole of the body is particularl
necessary when a rash is present. Toxæmia, sore
throat, and a rash may suggest an acute specific feve
until a full examination reveals an incompletel
healed sore on the penis and enlarged lymphati
glands. It is sometimes advanced as an excus
that the patient objected to some special examinatio
But if he cannot be convinced that the examinatio
is necessary his case had better be abandoned, for
is better to lose a patient than lose a reputation.

Unavoidable Mistakes

Our critics may inquire if any such exist. The
is certainly room for such a category. There a
occasions when, according to sound principles, y
are wrong, but right by mere chance; and, aft
all, we are judged by results. There are occasio
when mistakes are avoided by sheer good luck, a
occasions when mistakes occur on such relative
unimportant occasions that happily the only resu
is a determination never to make them again.

An old man was sent into hospital for sciatica
six weeks' duration. He had no sign of scia
neuritis, he was labelled neurotic, and was on t
eve of discharge with a somewhat uncomplimenta
diagnosis when an enterprising house physician ask
for a radiogram of the spine to exclude new growt
There was no new growth, but the radiogram reveal
an ununited fracture of the femur, and althou
there was clinically no evidence of a fracture, excepti
the pain of which he complained, and no history
any accident or injury which might be held respo
sible, had he been discharged and subsequent
investigated elsewhere there would have been
excuse for the error and no mercy for the perpetrato

There are some diseases and lesions with su
anomalous and contradictory signs that in th
diagnosis it would be wrong to be right. Take int
cranial tumours, for example, and let me quote
few mistakes admitted by a master of his art.
pineal tumour with no sign of genital hypertrophy
precocity. A tumour of the corpus callosum, un
companied by headache, vomiting, or optic neurit
regarded as a case of hysteria. Another in the corp
quadrigemina which ran to its termination witho
palsy of ocular movements, auditory disturbance,
cerebellar symptoms. One recalls the famous rebu
of Samuel Gee to a clinical clerk who had darin
assumed the existence of two symmetrical cent
abscesses in the fronto-parietal regions which auto
showed to be the actual lesion. "You were rig
you see, but—you had no business to be!"

INDUSTRIAL ACCIDENTS IN THE IRISH FREE STA
The report for 1931 under the Factories and Worksh
Act, recently issued, states that the number of accide
notified in the Irish Free State during the year was 7
as compared with 860 in 1930, and 1288 in 1929. Fa
accidents were 9 in number, compared with 12 and 23
the two preceding years. The largest number of accident
182, or 24·7 per cent.—occurred in the locomotive build
trade.

TESTS FOR RESPIRATORY EFFICIENCY

WITH SPECIAL REFERENCE TO THE MERCURY U-TUBE

By Alan Moncrieff, M.D., M.R.C.P. Lond.*
PHYSICIAN FOR DISEASES OF CHILDREN AT THE BOLINGBROKE HOSPITAL

(From the Physiological and Out-patient Departments, Middlesex Hospital, London)

The need for some straightforward methods of estimating the degree of efficiency or failure of the respiratory apparatus has been expressed by many writers, dating from the first spirometric experiments of Jonathan Hutchinson.[1] Dyspnœa is essentially a subjective phenomenon, and from the rudimentary method of taking the number of pillows required for comfort as a guide to the degree of failure of the combined cardiovascular and respiratory systems to more complicated methods of testing the ventilation capacity, &c., clinicians and physiologists have sought to find some objective standards. The literature is strewn with suggested methods, mostly discarded for various reasons. In recent years a more urgent need for some way of estimating the state of efficiency of the respiratory apparatus has arisen in connexion with the development of thoracic surgery. R. A. Young,[2] in the Lumleian lectures for 1929, referred to various points with regard to the selection of patients for operations on the chest, and in 1930, at Winnipeg, he[3] spoke of the assessment of the patient's suitability and capacity. He referred to the high standard set by urological surgeons in respect to efficiency tests of the system with which they proposed to interfere, and expressed an opinion that there was scope for research into the measurement of respiratory efficiency. He suggested, for example, estimations of the vital capacity and tidal air and their relationship. The work here reported and other work in progress is an attempt to carry out such research.

Renal efficiency tests are performed as routine measures before major operations on any part of the genito-urinary system. Such tests are based upon physiological conceptions of the normal functional capacity of the system, and have also a more limited sphere of usefulness in connexion with general medicine and obstetrics. Respiratory efficiency tests have so far lamentably failed to give any but the slightest help to physicians or surgeons engaged in clinical problems. Not only would some means of estimating the degree of respiratory failure be of great value in patients before any surgical procedure was carried out on the lungs, but there would also be very valuable applications in other branches of medicine and surgery. Quantitive estimation of the progress in cardiovascular failure would be aided by such tests, while in the industrial field disability in cases of silicosis might be assessable by some such means. In treatises on the surgery of the lungs there is for the most part no mention whatever of any tests for respiratory efficiency. Morriston Davies[4] makes no mention of the possibility of such tests. Alexander,[5] in his monograph, speaks of the dangers in the early days of thoracoplasty operations when many patients died of acute respiratory insufficiency, but in his otherwise excellent account of pre-operative preparation he does not refer to investigation of the capacity of the patient's respiratory apparatus.

Various Types of Test

It is proposed in the first instance to discuss what tests are already available which have some basis on physiological conceptions. There are, firstly, various elementary points which can be determined on a routine clinical examination, such as respiratory rate, whether accessory muscles of respiration are in use, size of chest. degree of pathological lesion, together with blood counts, especially estimation of hæmoglobin, and possibly also determination of blood-gases in arterial and venous blood. Most of these methods of estimating respiratory efficiency are, of course, employed at the present time, and a judicial summing up of evidence thus afforded enables the trained clinician to reach a fairly satisfactory conclusion. It must be noted, however, that so many factors are concerned in producing deviations from the normal in any of these methods that results obtained are necessarily haphazard and in many instances quite unsatisfactory.

A second series of tests for respiratory efficiency are concerned with measurement of the vital capacity and its component parts. the tidal air, supplementary air, and complementary air. The advantage of such tests is that it requires very little training for a patient to be able to blow into a spirometer and exact figures are easily obtained as to the quantitative capacity of the lungs. The disadvantage of such tests lies in the difficulty of knowing the normal standards for individual patients. The formula devised by Dreyer,[6] for example, has been criticised by subsequent writers, and no measurement of the lung volume can be complete without a knowledge of the residual air, the estimation of which requires a more complicated proceeding not always applicable to the sick patient. The estimation of the "dead space" of the lungs is another possible method of arriving at an objective measurement of the degree of respiratory failure for, as Haldane[7] and others have emphasised, this "space" must be regarded as a physiological rather than as a strict anatomical conception. The estimation of lung volumes requires a satisfactory spirometer, preferably of the recording type, and for patients suffering from disease of the lungs it is essential that observations are not prolonged. Sampling of the alveolar air by any of the usual methods is generally very difficult with untrained subjects, and many of the results are unreliable unless the exact tidal air volume is known at the same time. Work on this aspect of the subject, where a ten-minute experimental period is used to obtain the vital capacity and, by means of sampling the alveolar air from the mouth-piece of the apparatus, figures from which the "dead space" can be calculated, is in progress and will be the subject of a future communication.

A third series of tests for respiratory efficiency are concerned with various "indices" devised principally to give some idea of the ventilating power of the respiratory apparatus. Some of these were discussed in two previous papers,[8, 9] where a new index, "the ventilation equivalent for oxygen," was described. Other possible methods in this group include the "dyspnœa ratio" of Hunt and Dufton,[10] the "factors" devised by Bazett[11] for testing the respiratory efficiency of air pilots, and, more recently, the "ventilation index" of Harrison and others.[12, 13] The advantage of such methods is that they provide a numerical statement of the degree of respiratory efficiency or failure, but the grave disadvantage is present for all of them that normal figures may provide a too rigid standard, and wide deviations

---

* Working with a personal part-time grant from the Medical Research Council.

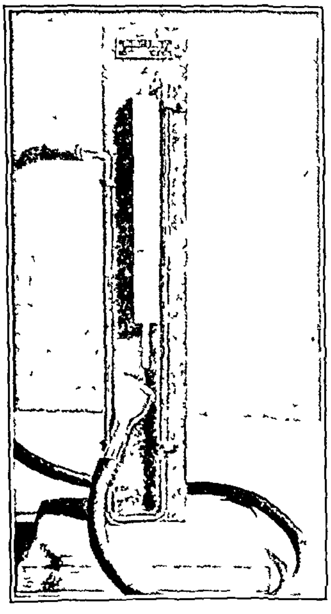
may be possible in health. Further, there is a danger that a figure calculated from some mathematical formula may be regarded as giving information which is not justifiably deducible from the original data. For example, in all discussions on the ventilating power of the lung there is always the need for correlating the actual ventilation to the body's requirements as regards oxygen intake and carbon dioxide output at that moment. The patient with diabetic coma will show a "ventilation equivalent for oxygen" many times the normal, but this is no indication that the respiratory apparatus is inefficient. It is necessary, however, to bear in mind these various formula to see whether, taken in conjunction with other data, they may prove of value.

Lastly come determinations of the expiratory force and sustaining power of the respiratory apparatus as tested with the mercury U-tube. This test, which has the great merit of simplicity, and is easy to apply to untrained subjects, was apparently first used by Stephen Hales,[14] who described in 1769 a method of measuring the force of respiration by means of an "inverted syphon" filled with mercury. The test has been used in modern times by various workers since its reintroduction by Flack[15, 16] for use in connexion with standards of respiratory efficiency for air pilots. It has been used for the investigations with which this paper is concerned, and its value will be discussed below in more detail.

Mercury U-tube Tests

The apparatus (Fig. 1) employed is a piece of stout capillary glass tubing with a bore of approximately 1·5 mm. in diameter. Each limb of the tube is 30 cm. long, joined by the lower ends to form a U-shape. The upper end of one limb is turned at a right angle to produce a side-piece about 3 cm. long, to which rubber pressure tubing 2 to 3 ft. in length is attached. Into the free end of this is inserted a glass mouth-piece consisting of a small funnel, flattened, with a small bar connecting the two flanges across the middle to prevent the subject from obstructing the opening with the tongue. The U-tube is mounted on a wooden frame, in the middle of which is fixed an adjustable scale reading in millimetres. The mouth-piece is kept hanging into a solution of lysol between each experiment, and is washed in water and dried immediately before use. Other requirements are a stop-watch and a nose-clip.

FIG. 1

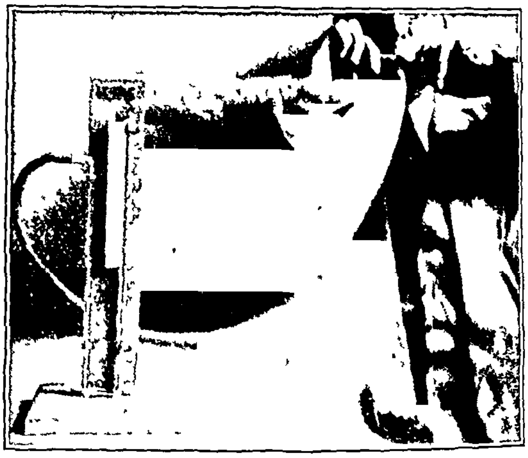


Flack's U-tube. Photo by the makers, Hawksley and Sons, London.

The subject is seated before a table on which the apparatus stands (Fig. 2). In the present investigation no attempt has been made to conceal the scale from the subject, who was invited to cooperate as heartily as possible in the proceedings. Two tests with the mercury U-tube were carried out following the instructions laid down in the pamphlet issued by the Air Ministry ("The Medical Examination fo Fitness for Flying"[17]). These instructions are a follows :—

"*Measurement of expiratory force.*—The subject i instructed to hold his lips round the mouth-piece with th thumb and forefinger of each hand, at the same time pressin against the cheeks. After drawing in a full inspiratio through the nose, he is told to blow the mercury *steadil as high as possible, strongly contracting* the abdomin muscles during the process. *On no account must the subje be allowed to swing the mercury up violently nor to persu in trying to force it up after it has started to fall.* The reaso for holding the cheeks is that it has been found that in som cases the mercury may be forced up to abnormal heights b the action of the cheek muscles. The number of mm H reached by the person's best efforts is recorded." (Italic in original.)

FIG. 2



The U-tube in use.

In the present experiment a preliminary "tria blow" to feel the weight of the mercury wa permitted, followed by three efforts, the best which was recorded.

The second test is carried out as follows :—

"*Endurance test (40 mm. mercury U-tube test).*—With th *nose clipped, the candidate is asked to empty* the lung completely, inhale fully, blow the mercury to the height 40 mm. and maintain it there without breathing as long a possible, the pulse being counted in periods of five second during the performance of the test."

The resting pulse was recorded at the beginnin of the preceding test for measuring the expirator force and again between the two tests, the paus being prolonged until the pulse-rate was the sam as at the beginning. Only one effort was allowed i this second test, as fatigue and repetition introduc complicating factors.

The subjects used in the investigation were draw from the casualty medical department of the Middlesex Hospital.† Only those patients with no obviou disease of the lungs or cardiovascular system wer used, and the various diseases from which the subjects for the test suffered included skin disorders arthritis, all forms of functional abdominal com plaints, neuralgia, sciatica, giddiness, and variou types of "nervous depression." The patient were invited "to have their lungs tested," an altogether 103 patients were examined, 39 men and 64 women, this sex difference being due entirely to the predominance of women at the out-patient sessions when the tests were performed. The average ages were 35 for the men (limits 17 to 66) and 42 for the women (limits 21 to 70).

---

† For permission to do this I am indebted to the medica committee of the Middlesex Hospital. To the casualty officer who have helped me to select subjects I am also deeply gratefu

The patients were all presumably "healthy" as regards their respiratory apparatus, but could not be regarded as very "fit" in a general sense for, with the exception of certain of the patients with skin diseases, they would not otherwise have been attending hospital. They can, however, be regarded as a fair sample of the "hospital population," and should serve as a basis for standards for tests which it is proposed to apply to similar patients with disordered respiratory function. There are several fallacies, however, about using patients suffering from "nervous depression," or from abdominal complaints, which will be discussed later.

RESULTS

Expiratory force.—The average for all the men was 88 mm. Hg, with limits of 55 to 120 mm. Hg. For the women these figures were 51 mm. Hg, and limits 20 to 100 mm. Hg. Among the 64 women, however, were 10 who have been labelled "non-coöperators," as they would not really try to carry out the test, and their results were poor. Excluding these, 54 women gave an average of 58 mm. Hg, with limits 30 to 100 mm. Hg. According to the Air Force standards the average for normal persons is about 110 mm. Hg, and under 80 mm. is considered to indicate respiratory inefficiency. Of the present series 11 out of 39 men failed to reach 80 mm. (28 per cent. failures), and only 3 of the women reached 80 mm., representing a failure rate of 94 per cent., excluding the non-coöperators.

Endurance test (40 mm. mercury test).—Among the men there were 3 "non-sustainers"—i.e., subjects who could not keep the Hg at the level of 40 mm. for longer than a few seconds. The remaining 36 men gave an average of 33 seconds (limits 15 to 56 seconds). Among the women the 10 non-coöperators were excluded from this second test, and there were a further 17 non-sustainers. The remaining 37 women gave an average of 24 seconds (limits 15 to 55 seconds).

FIG. 3

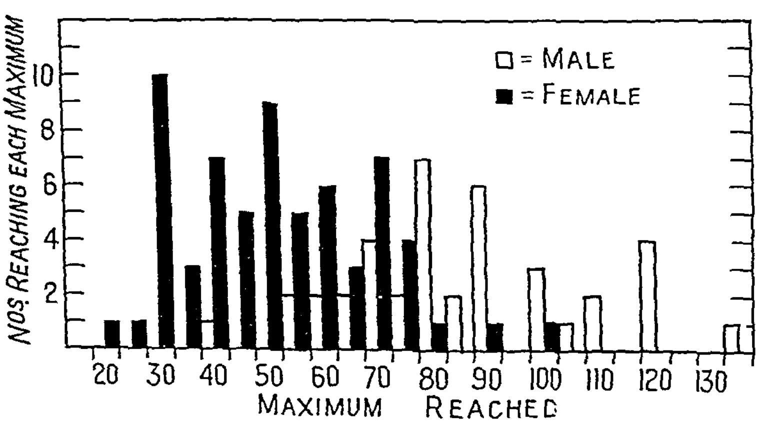


Chart showing the maxima reached in the expiratory force test.

According to the Air Force standards the average time should be between 50 and 60 seconds, and "a time less than 40 seconds is very unsatisfactory." Of the present subjects 25 of the men failed according to these standards (69 per cent.), and only 1 woman passed over 40 seconds. The results of these two tests are represented graphically in Figs. 3 and 4.

FIG. 4

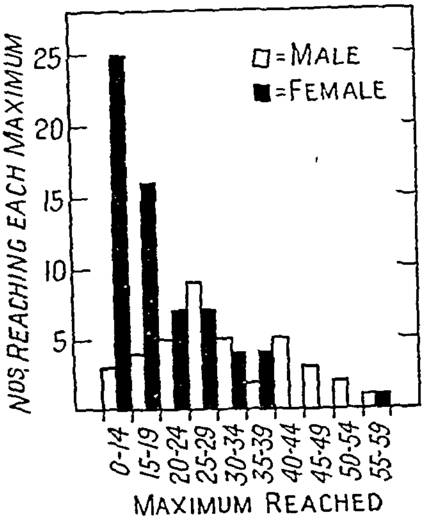

Chart showing the maxima reached in the sustaining 40 mm. Hg test.

In connexion with the endurance test the pulse response is regarded as being of equal if not of greater importance than the actual time achieved. According to the Air Force standards "a large rise in pulse-rate, e.g., from 72 to 132 or 144, is unsatisfactory." We have taken the pulse rate in the second and third period of five seconds from the beginning of the test as a basis for estimating the pulse response of the subject, since in most instances these periods gave the highest pulse readings. Of the 36 men, 7 showed a pulse-rate of 132 or over in one or other or both of these five-second periods. Two of these, however, were nervous subjects with a resting pulse of 144 and 120 respectively. Hence it may be said that only 5 failed (14 per cent.) in this test on the basis of the pulse response. Among the 37 women there were 6 in whom the pulse reached 132 or over in the second or third (or both) five-second periods. One of these had a resting pulse of 108, so that in this group there were likewise five failures.

Reviewing these results as a whole, it is obvious that the number of patients examined is small, but since no selection was made except on the lines laid down, the results do represent roughly the respiratory efficiency of the hospital population *as viewed against the standards of the Air Force.* The psychological factor is an important one in these tests and the urge to succeed was absent in many subjects, noticeably those with various forms of nervous depression. The importance of the abdominal muscles in the tests must also be remembered, and it may be that patients with abdominal pains of whatever origin may not give the response that they might do in perfect health. (In none of the patients tested was any pain present at the time of examination.) The best response (55 seconds) among the women in the endurance tests came from a patient, aged 26 years, who was a singer and a swimmer, while another woman patient of the same age, also a singer, could only manage 17 seconds. Both of these subjects expressed self-satisfaction with their power to control the respiratory apparatus, and their subjective similarity was in striking contrast to the objective differences obtained. A male subject who managed 120 mm. Hg in the expiratory force test could only sustain for nine seconds, and he explained his disability as due to his having been severely gassed in the war. Apart from this single big difference, it may be remarked, that, in general, the results of the two tests ran parallel.

It should also be noted with regard to the poor results obtained in the endurance test that the level of 40 mm. Hg was used throughout, unless the subject had only reached a lower level with the expiratory force test. Obviously with an average for the latter test of 100 mm. Hg in the Air Force standard the level of 40 mm. for the endurance test is a long way below the maximum possible. In a series such as this with averages of 88 mm. (men) and 51·2 mm. (women) the 40 mm. level is approaching much too closely to the maximum. In certain cases it actually represented the maximum effort obtained.

Comparison of the results obtained is therefore not strictly possible, but the Air Force standards are widely used as standards for respiratory efficiency, and it becomes important to discuss their ultimate value for the clinician.

PREVIOUS WORK

The physiological significance of the mercury U-tube tests has been explored by various writers. Flack and Burton [18] conclude as follows:—

> "Both tests may be taken as affording indication of the ventilation capacity of the individual and of his susceptibility, as manifested through the action of the medullary centres, to increase of carbon-dioxide and of diminution of oxygen in the alveolar air."

The pulse-rate during the test is also urged as important. Subsequent workers have dealt with certain other aspects of the question, and their conclusions will be briefly summarised. Hambley and McSwiney [19] used a modification of the endurance test, counting the pulse-rate before and after the mercury had been held at 40 mm. for 20 seconds. They reported differences in the response obtained according to whether the subjects were fatigued or not. Cripps,[20] in a valuable report, gives the results of applying the Air Force efficiency tests to men and women. She took the results obtained from over 1000 candidates for the Air Force, and compared these with results from nearly 500 women (students at Bedford College, students at the South-Western Physical Training College, and a group of civil servants). For the women she reduced the level of mercury for the endurance test to 20 mm. of mercury, so her results are not strictly comparable with those here reported. She found uniformly lesser mean values in women than in men. The Bedford College students gave slightly better results than the other groups, and these were, for the respiratory force, an average of approximately 78 mm. Hg, and for the endurance test (20 mm. Hg) 45 seconds. Warner and Hambley [21] studied the physiological mechanisms in association with the endurance test at 40 mm. Hg. They emphasise the importance of good abdominal tone for success in this test. With Pembrey [22] the same authors investigated various aspects of physical fitness, using the endurance test as one of several tests. They concluded that the mercury manometer test (at 40 mm.) was not a test of physical fitness, and emphasised that the pulse records in association with exercise afforded the best test for general physical efficiency. Schneider,[23] working in connexion with the American Air Force, has discussed Flack's two tests. He thinks the test for expiratory force is unquestionably a measure of the power of the abdominal and other expiratory muscles. The endurance test for his subjects gave an average of 52·2 seconds. He mentions the importance of practice in these tests, and thinks that both tests require too much voluntary attention and hearty coöperation on the part of the patient, both tests being to some extent psychological.

Discussion

In discussing tests for the efficiency of any system of the body it is important to determine at the outset some sort of answer to the question "efficient for what purpose?" Lungs which might be regarded as inefficient for air pilots, flying at high altitudes, may still carry out their functions perfectly for the civilian population, and although inefficient by Air Force standards, a patient's respiratory apparatus may yet be in a healthy enough state to stand operative interference without failure. Flack,[16] in his enthusiasm for the subject of respiratory efficiency, attempted to suggest that the averages obtained from Air Force pilots and cadets could be adopted as standards for the general community. Such generalisation would seem as a result of this small investigation quite unjustified. Cripps [20] is also strongly of this opinion in her report, and indeed she questions whether physiological respiratory tests can be used as guides to the particular conditions they have been held to interpret. It seems justifiable to conclude that even if Flack's tests are applicable as tests for respiratory efficiency, fresh standards for the general population, and especially for the less physically fit members of the population, must be determined before they can be applied to the problems outlined in the introductory section of this paper. The variations were enormous in the present series, the psychological influence was strongly marked in many subjects, and taken alone Flack's tests have really afforded very little help in arriving at some answer to the questions—is this patient's respiratory apparatus functioning properly? And, if not, what is the degree of failure?

Summary

The various tests which have been employed for estimating the efficiency of the respiratory apparatus are described and briefly discussed. The results of a special investigation of the mercury U-tube tests of Flack for a group of hospital patients are given. It is shown that so many factors enter into the results of these tests, psychological as well as the efficiency of other systems and parts of the body such as the abdominal muscles, that taken alone such tests have probably little value for the special purpose of investigating respiratory efficiency before thoracic surgery is carried out. In any case the standards set out by Flack for the Air Force appear to be far too high for the ordinary population attending hospital. Standards for this population are suggested in this paper but are based upon only a very small number of patients. Further work is in progress in connexion with this point and with other tests for respiratory efficiency.

I am indebted to Dr. R. A. Young for much encouragement and to Prof. Samson Wright for his helpful criticisms and permission to work in his department.

VITAMIN-A RESERVES OF THE HUMAN LIVER IN HEALTH AND DISEASE

WITH SPECIAL REFERENCE TO THE SCOPE OF VITAMIN A AS AN ANTI-INFECTIVE AGENT

By T. Moore, D.Sc. Belf.
OF THE M.R.C. NUTRITIONAL LABORATORY, CAMBRIDGE

The experiments described below were carried out with two main objects: (1) to obtain information as to the vitamin-A reserves of inhabitants of this country, similar to that made available in Holland by L. K. Wolff,[1] and (2) to examine how far the observation of low vitamin-A reserves can be correlated with any particular type of pathological picture. Mellanby and Green[2,3] have suggested that vitamin A may be of clinical importance as an anti-infective agent, and on this assumption some correlation between infection and low vitamin-A reserves might be expected.

VITAMIN A IN THE RAT

Although the present work deals with the vitamin-A reserves of human subjects, a brief summary of our knowledge of the action and economy of this vitamin in the rat will indicate the nature of the problems to be attacked.

(1) Except for small amounts distributed fairly evenly throughout the body fat, the main reserve of vitamin A is concentrated in the liver. This reserve behaves as a system quite distinct from the storage fat reserves of the body, and may persist undiminished during extreme emaciation.

(2) The extent of the liver reserve may vary over a range of amazing elasticity. On a diet rich either in vitamin A or carotene (provitamin A) a reserve calculated to be sufficient for a century (33 times the normal life period) may sometimes be collected.

(3) Restriction of the rat to a diet deficient in vitamin A leads eventually to the complete exhaustion of the reserves (provided the preliminary level has not been too high), and the development of a state of avitaminosis in which the keratinisation of epithelial tissues throughout the body is the main pathological feature (see L. J. Harris[4]). In this condition the animal becomes particularly susceptible to infection.

(4) If no treatment is given death may result through emaciation without macroscopic evidence of infection, but more frequently the condition is terminated by gross infection—e.g., of the lungs or renal system. Xerophthalmia, the classical syndrome of vitamin-A deficiency, is frequently, but not invariably, observed.

(5) On the other hand the rat may be cured, with restoration of growth and of every outward sign of well-being, by the timely administration of vitamin A in amounts too small to permit the accumulation of a reserve in the liver.

(6) Although deficiency of vitamin A leads to the increased susceptibility to infections, high reserves do not necessarily ensure protection. Occasional cases of fatal infections may be observed in rats possessing abundant stores of the vitamin.

Thus in the rat vitamin-A reserves varying from nil to very high values may be consistent with apparently normal health. It is therefore only to be expected, as Wilson[5] and Wolff have shown, that the vitamin-A reserves of human subjects should vary over a wide range. At the same time it is questionable whether the human would be able to maintain normal health over prolonged periods when the vitamin-A reserve is seriously depleted. In the first place it must not be forgotten that the experimental rat lives a life of complete ease in a room kept at constant temperature, and is thus protected both from fatigue and from the sudden climate changes, which so often mark the initial point of illness in the human. If the enormous apparent superfluity of vitamin A capable of accumulation in the liver serves any immediate purpose, as opposed to representing provision for the distant future, it is conceivable that a level of "optimal" as opposed to "*minimal*" vitamin action may exist. In this case an increased store of vitamin A might be a deciding factor in assisting the animal to withstand the strains of ordinary life. Secondly, the experimental rat receives a diet which is designed to be adequate in all dietary factors other than vitamin A. In the human, on the contrary, the observation of a low vitamin-A reserve must almost inevitably imply that the dietary was also inadequate, possibly to a more acute degree, in several other factors. Thus vitamin A in many of its common sources has a distribution similar to that of vitamin D, while carotene (provitamin A) and vitamin C are found together in green vegetables. In the human, therefore, a low vitamin-A reserve must often be an indication of general malnutrition. The main interest in the present work indeed might be said to rest in the broad indications of those diseases which seem to be associated with nutritional abnormalities, rather than in the incrimination of vitamin-A deficiency as the specific ætiological factor involved.

Experimental

Weighed specimens of human liver were obtained at autopsies.

These were supplied through the kindness of Prof. J. Shaw Dunn, Royal Infirmary, Glasgow; Dr. W. M. Elliott, Ruchill Fever Hospital, Glasgow; Prof. E. H. Kettle, St. Bartholomew's Hospital, London; Prof. R. Muir, F.R.S., Western Infirmary, Glasgow; Miss Dorothy Russell, London Hospital; Prof. M. J. Stewart, General Infirmary, Leeds; Prof. H. M. Turnbull, London Hospital; and Dr. C. G. L. Wolf, Addenbrooke's Hospital, Cambridge, to whom I am also indebted for the description of the cases. The specimens were preserved in dilute aqueous potash and were posted to Cambridge in small bottles. Preliminary experiments proved that the vitamin-A content was not affected either by reasonable delay between death and autopsy or by prolonged storage in alkali.

In extracting the liver oil a simplified modification of the usual alkali digestion process was employed. The vitamin A was then estimated by the antimony trichloride method, the results being calculated in blue units per gramme of fresh liver according to the scheme previously adopted.[6]

CLASSIFICATION OF CASES

Classification has been carried out according to disease under two schemes. In the main scheme (Table I., Fig. 1) each case examined (with the exception of a few cases having rare specific diseases, which have been omitted from consideration in the present communication) has been included once only in its most appropriate group as indicated by the primary disease. This disease, of course, may be distinct from the terminal lesion—e.g., cancer cases would be classified as such although the actual cause of death might be pneumonia, peritonitis, or post-operative collapse. The second subsidiary scheme (Table II., Fig. 2) concerns only certain diseases having special interest. Classification in this scheme has been restricted to those cases in which mention of these diseases is made, and where necessary cases have been included more than once under several different diseases. In this scheme a hypothetical cancer case having pneumonia and peritonitis would be classified under both the latter headings.

TABLE I. (SCHEME I.)

Group.	Cases.	Diseases. (Figures in parentheses refer to number of cases.)	Vitamin-A reserve (b.u. per g.).		Sub/super-norm. ratio.
			Av.	Md.

TREATMENT OF RESULTS

In view of the enormous variations between the extreme values in any particular group it is essential that special treatment should be adopted in the examination of results. Although averages for each group have been given it will readily be understood that these values may be most deceptive, since one case giving a very high value could obscure the effect of several subnormal values, in which our main interest lies. (One case giving 2000 b.u. per g. would neutralise the effect of four completely deficient cases.) On the other hand, the *medial* value obtained by arranging the cases in order of ascending vitamin-A reserves and taking the case in the centre of the list (in practice the average of the 3–6 central cases, according to the size of the group) although not unduly influenced by the inclusion of extravagantly high values, will also fail to indicate the presence of interesting low values. It has therefore been necessary to resort to a diagrammatic method in order that the nature of the results may be clearly understood. In Figs. 1 and 2 each case has been represented by a narrow rectangle, the height representing the extent of the vitamin-A reserve per gramme of liver, the width being adjusted in an inverse ratio to the number of cases. The shapes of the diagrams provide a rapid means of comparing the results obtained in different diseases, while the degree of fineness of the indentations affords some indication of the relative reliability of the evidence.

THE "NORMAL" VITAMIN-A RESERVE: "SUB- OR SUPER-NORMALITY RATIO"

Although the range of variation of the vitamin-A reserve even in accident cases makes the conception of a normal value somewhat anomalous, it is necessary that some figure should be chosen provisionally in order to serve as a basis for the discussion of results. In the present work the medial value in the accident group (235 b.u. per g.) has been taken as the most logical choice for the "normal" value.

As a further device to assist in the summarisation of results a comparison has been made of the numbers of cases in each group falling above and below the "normal" value. The quotient of these two numbers gives the "normality ratio" for the group. In the accident group the value is unity. Other groups may show either sub- or super-normality ratio ranging from 0, which implies that all the cases fall below normal, to ∞, which means that all the cases are above normal.

Discussion

In work of the present character, which deals with material outside the scope of scientific control, great caution must be exercised in the interpretation of results. At the same time the aim of the investigator must be to seek out those directions which appear to hold out hopes of future progress.

GENERAL AVERAGE

For all the 325 cases examined an average value of 282 b.u. per g. was given. This may be compared with the value of 251 b.u. per g. given by Wolff as the average for 915 cases.* Unfortunately the magnitude of the error in the antimony trichloride method of assay, applied under slightly varied conditions in unrelated laboratories, makes it

---

* All values quoted from Wolff's paper have been increased by 10 per cent. to allow for a recognised difference in technique.

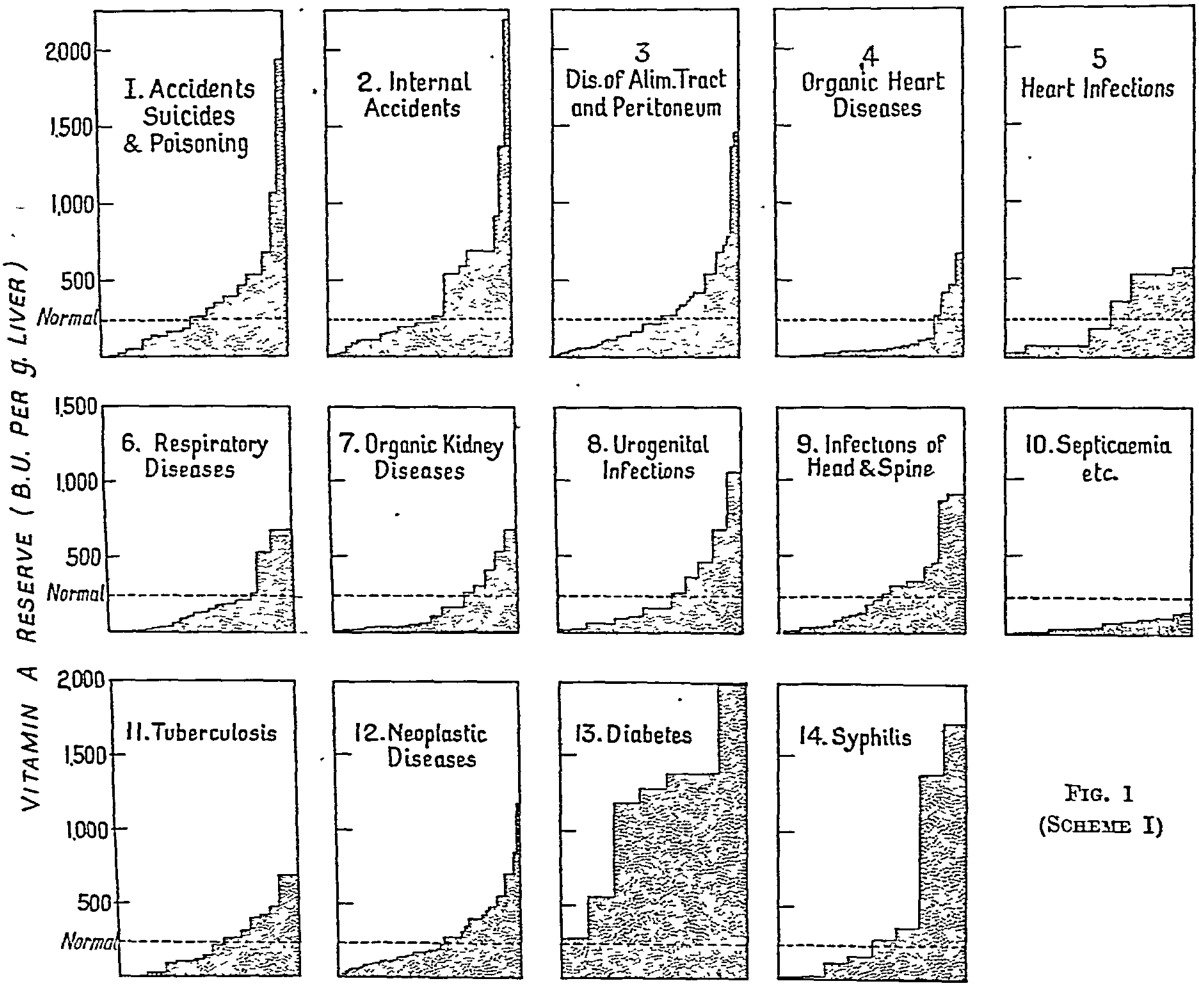

FIG. 1 (SCHEME I)

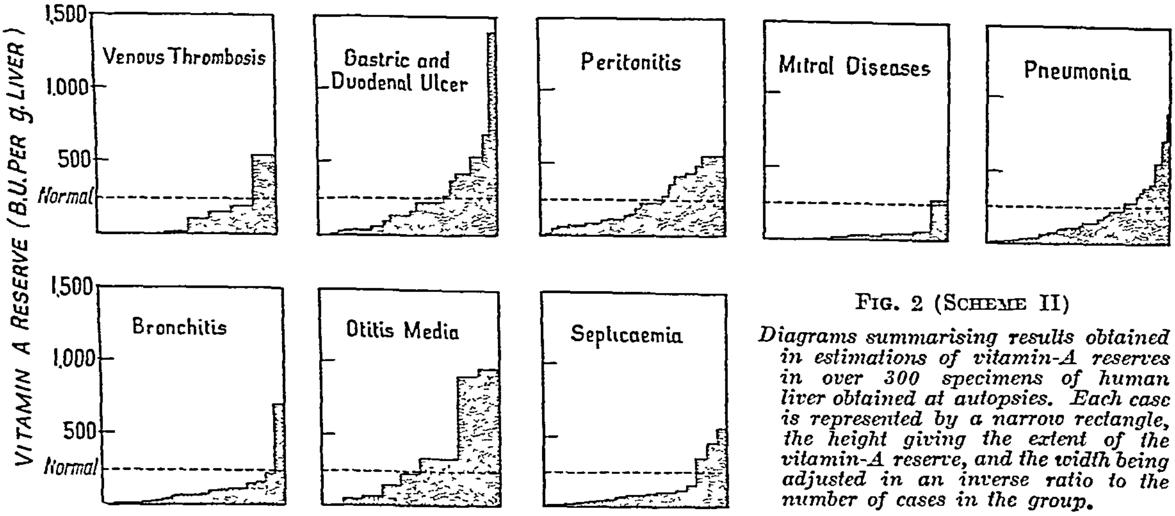

FIG. 2 (SCHEME II)

Diagrams summarising results obtained in estimations of vitamin-A reserves in over 300 specimens of human liver obtained at autopsies. Each case is represented by a narrow rectangle, the height giving the extent of the vitamin-A reserve, and the width being adjusted in an inverse ratio to the number of cases in the group.

impossible to decide whether this small difference is of real significance. Indeed if the two averages represented duplicate determinations on the same material the agreement is quite as close as could be expected. It would appear therefore that the average vitamin-A reserves of the populations of Holland and Great Britain, *at least as far as can be judged from results* relating to restricted localities, are of much the same order.

DISEASES ASSOCIATED WITH NORMAL VITAMIN-A RESERVES

From Table I. it will be seen that groups 2, 3, 5, 9, 11, 12, 14, including "internal accidents," diseases of the alimentary tract and peritoneum, heart infections, infections of the head and spine, tuberculosis, neoplastic diseases, and syphilis, gave normality ratios between 0·7 and 1, while group 8 (urogenital infections) gave a slightly lower ratio, 0·63. It seems improbable that the difference of any of these ratios from unity is of ætiological significance, particularly since Wolff has observed a much smaller gap between the average for 78 accident cases (270 b.u. per g.) and the average for acute and chronic diseases (248 and 227 b.u. per g., respectively). A small difference from the "accident" level might perhaps be anticipated in those diseases involving under-nutrition during prolonged decline.

It must be pointed out, however, that several of the diseases classified in the above groups (urogenital infections, gastric ulceration, otitis media) are often observed in the rat suffering from experimental vitamin-A deficiency. It might be unwise therefore to dismiss the possibility that a nutritional factor may have been involved in a small percentage of cases. Thus although data for nine cases of otitis media gave only slightly subnormal figures, the three lowest cases gave values of 0, 40, and 50 b.u. per g. It must also be remembered that in cases of more or less unknown history deceptively high values may sometimes have resulted through the therapeutic use of substances rich in vitamin A, notably cod-liver oil at a time when the condition of the patient had become too advanced to permit recovery. Wolff has suggested that his high values for tuberculosis may be due to this reason. As far as can be ascertained, however, in most of the cases examined in the present work the patients did not receive cod-liver oil.

SUPER-NORMAL VITAMIN-A RESERVES

The values observed in diabetes are of interest as evidence in support of the rational character of results obtained by the antimony trichloride method. Since green vegetables and carrots feature largely in the special dietaries to which diabetic patients are usually restricted it might be expected that the vitamin-A reserves would prove to be unusually high. In confirmation of Wolff's results this was found to be the case, the average reserve for the seven cases examined (1160 b.u. per g.) being about three times greater than the average given by the accident group.

DISEASES ASSOCIATED WITH SUBNORMAL VITAMIN-A RESERVES

Although group 3 (diseases of the alimentary tract and peritoneum) gave a ratio (0·72) pointing to close similarity with the accident group, somewhat lower ratios have been given by peritonitis (0·5) and by gastric or duodenal ulceration (0·42) when treated separately under Scheme II. Wolff however has reported rather high averages in these conditions, and the low values in this instance may be attributed to the inclusion of those cases in which these lesions are secondary to some other disease. The ratio in group 4 (organic heart disease) (0·2) however is decidedly subnormal, while under Scheme II. the ratio for 11 cases of mitral disease (0·1) is even lower. The *ratio in group 6 (respiratory diseases)* (0·3) is low, while under Scheme II. we find pneumonia (0·33) giving a low, and bronchitis (0·06) a very low ratio. In group 7 (organic kidney diseases) (0·42) the ratio is again low. The lowest ratio of all however is found in group 10 (septicæmia, &c.) (0), in which every case possessed a subnormal vitamin-A reserve. By the inclusion of certain cases from other groups—e.g., heart infections, head and spine infections—*the ratio rose to 0·2 for septicæmia treated under* Scheme II. Finally a low ratio was observed in eight cases of venous thrombosis (0·14). This finding is of interest in view of Green's observation of low vitamin-A reserves in several cases showing this condition, and of the low average (139 b.u. per g.) obtained by Wolff in seven cases of embolism.

In reviewing the results in the above diseases we may consider that the low values observed in respiratory diseases and in the septicæmia group lend *colour to the current view that* hypovitaminosis A may play some part in the ætiology of these conditions. Particular theoretical interest must be attached to the low values in bronchitis. It would appear that the localised proliferation and desquamation of the epithelial lining of the bronchi, which takes place in this condition under the influence of infection, is not to be confused with the widespread keratinisation of epithelial tissues throughout the body which is associated with infection in experimental vitamin-A deficiency. The present results, however, suggest the possibility that in hypovitaminosis A of insufficient severity to produce widespread keratinisation the bronchi may still fail to show normal resistance to bacterial invasion. It is of interest that Wolff has observed subnormal averages both in sepsis and broncho-pneumonia, although in each case the difference from the general average is less marked than that observed in the present work.

On the other hand, the observation of low vitamin-A reserves in organic heart and kidney diseases cannot readily be correlated with our present conceptions of the functions of the vitamin. The importance of the matter certainly demands that a much larger number of cases should be examined before definite conclusions are reached, but it is noteworthy that Wolff has observed averages decidedly below normal both in chronic heart diseases (102 cases, average 179 b.u. per g.) and chronic kidney diseases (54 cases, average 142 b.u. per g.). Since renal and cardiac inefficiency, together with bronchitis, often represent more or less closely related lesions in the same subject, it is of interest that all three diseases should be associated with subnormal vitamin-A reserves. Nevertheless it must remain undecided whether nutritional deficiency represents a genuine factor in the ætiology of these diseases. It is obvious that malnutrition may be of objective or subjective character, according to whether the diet is inadequate, or the powers of assimilation of the subject are at fault, either through failure to eat normal amounts of food or through the defective absorption of food constituents after ingestion. The frequent observation of adequate vitamin-A reserves in wasting diseases—e.g., cancer of the alimentary tract—suggests that failure to eat normal amounts of food, although probably causing a general lowering of values, may not completely account for the preponderance of disproportionately low values observed in heart and kidney diseases. It remains possible, however, that under certain conditions the liver may be unable to absorb or retain the vitamin A available in the food-supply. Wolff has obtained a low average (78) for six cases of cirrhosis of the liver, and suggests that the powers of retention may be impaired in this condition, but the average (784) obtained in the present work for the same number of cases, possibly of a different type of cirrhosis, does not support this view. The experiments of H. N. Green† on the treatment of septic puerperal cases with large doses of vitamin-A concentrate, however, afford definite proof that the absorption of the vitamin, as judged by the amount found in the liver post mortem, may sometimes be extremely inefficient, or even completely negative. The question of the exact significance of the present results must therefore be left open.

VITAMIN A AND INFECTION

From the fact that groups 3, 5, 8, 9, and 11, each of which includes a predominance of cases of infective type, give normality ratios differing only slightly from unity, it must be obvious that adequacy, or even abundance, of the vitamin-A reserve does not itself ensure protection from infection. To illustrate this point further a short representative list of infective cases possessing adequate vitamin-A reserves is given in Table III.

TABLE III

Case.	Sex and age.	Post-mortem report and history.	Vitamin-A reserves per g. liver.
56	F 35	Incomplete abortion and general peritonitis, duration 3 days. (Streptococcal.)	550
80	F 51	Infective endocarditis. 6 wks. history.	600
91	F 9	Organising lobar pneumonia of lt. lower lobe (4 wks. duration). Pneumococcal peritonitis (8 days). Infarct of spleen. Intense toxic visceral changes.	225
94	M 36	Empyema. Focal peritonitis with abscesses.	550
106	F 25	Double hydronephrosis. Cystitis. Pneumonia.	375
114	M 30	Purulent meningitis. Portal and systemic septicæmia. Gangrenous appendicitis.	450
122	M 23	Long-standing (1923) suppuration in lt. frontal and ethmoidal sinuses. Subepicranial suppuration. Subdural abscess (lt.). Leptomeningitis. Multiple abscesses.	475
144	F 3 11/12	Caseous tuberculosis of cervical and mediastinal lymph nodes. Advanced tuberculous broncho-pneumonia rt. lower lobe of lung. Acute miliary tuberculosis.	400
147	F 4/12	Tuberculous meningitis. Generally disseminated tuberculosis.	425

The action of vitamin A cannot therefore be described as anti-infective in an indiscriminate or "positive" sense. Vitamin-A deficiency would seem to be one of many errors which may lead to the same terminal infections. The action of the vitamin can only justly be described as anti-infective in a sense complementary to the fact that deficiency increases the liability to infection.

On the other hand, the very low results obtained in the septicæmia group suggest that hypovitaminosis A, or the low general standard of nutrition which it must imply, may be a factor of clinical importance in the ætiology of certain types of infection. In view of the comparatively small number of cases investigated, it is obvious that further work is necessary both to confirm this conclusion and to define more clearly the points of difference of these infections from others which seem to be associated with normal vitamin-A reserves. Thus it is difficult to understand why more or less normal reserves should have been observed in the case of the few septicæmias examined having foci in the heart or head. For the present however there seems little obvious connexion between the development of septic arthritis and osteomyelitis, the few available cases of which have shown a distinct tendency towards low vitamin-A reserves, and the familiar epithelial changes of experimental vitamin-A deficiency. While it seems quite possible that epithelial lesions may represent only one aspect of the pathology of avitaminosis—or hypovitaminosis A—it must not be forgotten that the low vitamin-A reserves may be a reflection of some more acute deficiency producing lesions of an entirely different character. In view of the site of these diseases, the possibility of hypovitaminosis C must at once come to mind.

THE PREVALENCE OF HYPOVITAMINOSIS A

Adopting the arbitrary value of 55 b.u. per g. as the level under which the vitamin-A reserve should be considered definitely subnormal, Wolff has shown that hypovitaminosis A is prevalent in about 16 per cent. of the total population of Holland, new-born infants being excluded. On the same standard the vitamin-A reserve in 24 per cent. of the cases examined in the present work would be considered inadequate. Table IV. shows the distribution of cases according to the amount of the vitamin-A reserve, expressed as a percentage of the "normal" value.

TABLE IV.—*Prevalence of Hypovitaminosis A*

Vitamin-A reserve. Per cent.	Percentage of total cases.	Vitamin-A reserve. Per cent.	Additive percentage of total cases.
0	3·7		
0–10 normal	9·5	Under 10	13·2
10–25 „	10·5	„ 25	23·7
25–50 „	18·8	„ 50	42·4
50–100 „	20·2	„ normal	62·4
Over normal	37·5		

Although the powers of absorption of the subject must have some effect in determining the extent of the vitamin-A reserve, it is obvious that the wide individual variation must primarily be due to differences in dietary habit. Moreover, when we recall once more that the vitamin-A reserve must usually provide a rough indication of the adequacy of many other food components, it is obvious that the whole nutritional make-up of the individual must be considered a highly variable factor, the effects of which are at present largely undefined. Thus we know that acute deficiency in any particular vitamin will lead to lesions of a more or less well-defined character, but are unable to decide whether partial vitamin shortage can result in reduced resistance to disease without the appearance of characteristic lesions. It is perhaps of interest that although 12 cases possessing no measurable vitamin-A reserve were encountered in the present work, not a single instance of xerophthalmia, the classical syndrome of vitamin-A deficiency, was reported. On the whole the evidence presented above supports the view that malnutrition sufficiently pronounced to produce lowered resistance to disease may frequently exist in the absence of florid signs of acute deficiency.

---

† To be published in the next issue of THE LANCET.

Summary

1. Vitamin A has been determined in over 300 specimens of human liver, obtained at autopsies, by means of the antimony trichloride method.

2. The vitamin-A reserve varied over an extremely wide range even among healthy subjects dying from accidental causes. The medial value for a group of accidental cases has been taken as representative of the "normal" vitamin-A reserve.

3. The ranges of vitamin A found in different diseases have been compared by a diagrammatic method, and by taking the ratio of the number of cases falling above and below the normal vitamin-A reserve.

4. Normal ranges of vitamin-A reserves were observed in the following groups of diseases: "internal accidents" (aneurysms, hæmorrhage, intestinal strangulations, &c.), diseases of the alimentary tract and peritoneum, heart infections, urogenital infections, infections of the head and spine (including otitis media), tuberculosis (all forms), neoplastic diseases (all forms), syphilis (all forms). In the case of some of these diseases involving chronic infection—e.g., tuberculosis—it is possible that deceptively high values may have resulted through the administration of cod-liver oil after the condition of the patient had become too advanced to permit recovery. This possibility is less probable in the case of acute infections.

5. Vitamin-A reserves much above normal were observed in cases of diabetes which had received dietetic treatment.

6. Vitamin-A reserves tended to be subnormal in the following groups: organic heart diseases, non-tuberculous respiratory diseases (particularly bronchitis), organic kidney diseases, and in septicæmias and certain septic conditions. It must not be forgotten that in some of these diseases vitamin-A subnormality may have been a secondary effect rather than a predisposing cause.

7. Since adequate vitamin-A reserves were frequently observed in a wide variety of infective conditions, it is plain that vitamin A should not be regarded as a positive anti-infective agent, indiscriminate in action. The term "anti-infective" is only justifiable in a sense complementary to the fact that deficiency of vitamin A leads to subnormal powers of resistance. The trend of the present work suggests that partial vitamin-A deficiency, or the state of multiple malnutrition which it must usually imply, may be of importance in the ætiology of some types of infection under clinical conditions.

My thanks are due to Dr. L. J. Harris for his interest and helpful criticism, to Dr. J. R. M. Innes for assistance in the classification of cases, and to Mr. A. Davies for technical assistance.

A CASE OF
SIMPLE CYST OF THE LIVER
WITH AN ANALYSIS OF SIXTY-TWO OTHER CASES

BY DAVIS A. BEATTIE, M.B. LOND.
SENIOR HOUSE SURGEON, METROPOLITAN HOSPITAL, LONDO
AND
H. D. ROBERTSON, M.R.C.S. ENG.
CASUALTY OFFICER AT THE HOSPITAL

IN view of the comparative rarity and uncerta ætiology of simple cysts of the liver, the followi case may be of some interest.

CASE NOTES

Mrs. A., aged 35, came up to hospital complaini of "abdominal pain."

History of present condition.—Eight weeks ago she fi began to have pain in the abdomen, in the region of t umbilicus. The pain was intermittent in type, coming in "sharp twinges." It was stationary in the umbilical ar and was not referred to the shoulder, groin, or back. was unrelated to meals and to exercise, but was wo towards the end of the day. The spasms of pain w described as "burning" in character, and lasted as a r for ten minutes at a time. Except for the pain she has had any other symptoms. She had not noticed any swell of her abdomen, and had never had any jaundice "shivering attacks." She had never had any trouble w micturition or noticed anything wrong with her uri Her bowels were open regularly every day. Her peri were normal, the last one being about a fortnight bef her arrival at hospital.

Condition on examination.—The abdomen was somew distended in the right upper quadrant, the fullness extend from the costal margin above to the level of the umbili below. On palpation this distension was found to be to a cystic swelling, spherical in shape, and about five inc in diameter. The cyst appeared to be movable quite fre in the abdominal cavity for about six inches in all directi It was not possible to replace the tumour into the ri loin or into the pelvis. On careful palpation it appea possible to separate it from the liver above it. On percuss it was continuous with the liver dullness above, and did appear to be continuous with the stomach percussion n It moved with the liver on respiration. On auscultation succussion splash was heard. Rectal examination revea nothing. Vaginal examination showed that the cyst not move with the cervix, when the latter was manua displaced.

Radiological report.—Before operation the patient radiographed to determine the relation of the swelling the alimentary tract. A barium meal of the stomach duodenum was performed, and the report was as follo "The swelling lies laterally to the right side of the stom and has displaced the stomach and the first part of duodenum to the left, but not forwards or backwa The colon is also crowded up inside the left diaphra which is displaced upwards. The stomach showed de in emptying, whether lying or standing, but was. dilated."

Operation was performed on Jan. 26th, 1932. The abdo was opened through a right paramedian supra-umbil incision. A large bluish cyst was seen projecting fr under the lower border of the liver, lying on the left of the gall-bladder, and covered with the same layer peritoneum. The falciform ligament was seen running on to its surface, slightly to its left side. The lower surf of the liver was expanded into a thin layer enclosing upper hemisphere of the cyst. The peritoneum was reflec from the surface of the cyst by gauze dissection, and latter peeled off the surface of the liver. There was connexion between the gall-bladder or any of the bili passages and the cyst. The redundant peritoneum then excised, and the remnant was marsupialised by sew it to the parietal peritoneum. The cavity was then pac with ribbon gauze to control the slight amount of ooz which took place, and the abdominal wound closed layers.

Pathological report.—The cyst appears to be a sim cyst of the liver. It contained 20 oz. of straw-colou slightly opalescent, and somewhat syrupy fluid. The in surface of the cyst was dull white in colour and smo with occasional fibrous trabeculæ on its surface. On sect the capsule was found to be composed chiefly of fibr tissue, with occasional blood-vessels. The cyst was li on its inner surface with non-ciliated epithelium of columnar-celled type. Chemical examination of the fluid showed it to be composed of a watery medium containing albumin, cholesterol crystals, and epithelial debris, but no bile-salts or pigments.

Post-operative progress.—The patient made an uninterrupted recovery. For several days after operation the sinus in the wound discharged a small amount of slightly blood-stained serum, but this eventually ceased, the sinus closed, and she was discharged from hospital on Feb. 27th with her wound healed and sound.

A REVIEW OF PUBLISHED RECORDS.

The original case of simple cyst of the liver was described by Gloz [1] in 1864. Since then a number of other cases have been reported, and in Table I. are a series of 62 cases collected from various sources. As well as these Schaack [2] mentions four cases in his paper—those of Weishaup,[3] Zindel,[4] and Margarucci,[5] who described two cases. Six cases have also been reported in Japan—those of Miyake,[6] Harada,[7] Fukue,[8] Minaki,[9] Kusakabe,[10] and Muto and Hanzawa.[11] A further eight cases have been recorded in various papers by Lowenburg,[12] Cassoute and Girbal,[13] Delbet,[14] Allende,[15] Sims,[16] Maes Urban,[17] Giardina,[18] and Harrington,[19] making a total of 80 cases reported up to the present time.

Classification.—There have been several attempts to classify these non-parasitic cysts of the liver, most of which are based on supposed differences in their mode of formation. Lippmann [20] differentiated them into the following groups: (*a*) cysts due to biliary stasis; (*b*) cysts with ciliated epithelium; (*c*) dermoid cysts; (*d*) multilocular cystic adenomata; and (*e*) lymphatic cysts. Thöhle,[21] however, simply divided them up into two main groups: (*a*) lymphatic and blood cysts; and (*b*) cystadenomata.

Probably the most accurate classification, however, is that of Sonntag,[22] which is generally accepted at present:—

(*a*) Blood and degeneration cysts.
(*b*) Dermoid cysts.
(*c*) Lymphatic cysts: due to obstruction or to congenital dilatation of the lymphatics.
(*d*) Endothelial cysts.
(*e*) Cysts due to bile-duct obstruction.
(*f*) Proliferative cysts: cystadenomata.

TABLE I.—LIST OF CASES

61	Rosenstein.	M.	47	(*a*) Multiple cysts of liver and pancreas.	Recovery.
62	Payr.	F.	25	(*b*) Right lobe.	"

Summary

1. Vitamin A has been determined in over 300 specimens of human liver, obtained at autopsies, by means of the antimony trichloride method.

2. The vitamin-A reserve varied over an extremely wide range even among healthy subjects dying from accidental causes. The medial value for a group of accidental cases has been taken as representative of the "normal" vitamin-A reserve.

3. The *ranges of vitamin A found in different* diseases have been compared by a diagrammatic method, and by taking the ratio of the number of cases falling above and below the normal vitamin-A reserve.

4. Normal ranges of vitamin-A reserves were observed in the following groups of diseases: "internal accidents" (aneurysms, hæmorrhage, intestinal strangulations, &c.), diseases of the alimentary tract and peritoneum, heart infections, urogenital infections, infections of the head and spine (including otitis media), tuberculosis (all forms), neoplastic diseases (all forms), syphilis (all forms). In the case *of some of these diseases involving chronic infection*—e.g., tuberculosis—it is possible that deceptively high values may have resulted through the administration of cod-liver oil after the condition of the patient had become too advanced to permit recovery. This possibility is less probable in the case of acute infections.

5. Vitamin-A reserves much above normal were observed in cases of diabetes which had received dietetic treatment.

6. Vitamin-A reserves tended to be subnormal in the following groups: organic heart diseases, non-tuberculous respiratory diseases (particularly bronchitis), organic kidney diseases, and in septicæmias and certain septic conditions. It must not be forgotten that in some of these diseases vitamin-A subnormality may have been a secondary effect rather than a predisposing cause.

7. Since adequate vitamin-A reserves were frequently observed in a wide variety of infective conditions, it is plain that vitamin A should not be regarded as a positive anti-infective agent, indiscriminate in action. The term "anti-infective" is only justifiable in a sense complementary to the fact that deficiency of vitamin A leads to subnormal powers of resistance. The trend of the present work suggests that partial vitamin-A deficiency, or the state of multiple malnutrition which it must usually imply, may be of importance in the ætiology of some types of infection under clinical conditions.

My thanks are due to Dr. L. J. Harris for his interest and helpful criticism, to Dr. J. R. M. Innes for assistance in the classification of cases, and to Mr. A. Davies for technical assistance.

A CASE OF
SIMPLE CYST OF THE LIVER
WITH AN ANALYSIS OF SIXTY-TWO OTHER CASES

BY DAVIS A. BEATTIE, M.B. LOND.
SENIOR HOUSE SURGEON, METROPOLITAN HOSPITAL, LONDON
AND
H. D. ROBERTSON, M.R.C.S. ENG.
CASUALTY OFFICER AT THE HOSPITAL

IN view of the comparative rarity and uncertain ætiology of simple cysts of the liver, the following case may be of some interest.

CASE NOTES

Mrs. A., aged 35, came up to hospital complaining of "abdominal pain."

History of present condition.—Eight weeks ago she first began to have pain in the abdomen, in the region of the umbilicus. The pain was intermittent in type, coming on in "sharp twinges." It was stationary in the umbilical area, *and was not referred to the shoulder, groin,* or back. It was unrelated to meals and to exercise, but was worse towards the end of the day. The spasms of pain were described as "burning" in character, and lasted as a rule for ten minutes at a time. Except for the pain she has not had any other symptoms. She had not noticed any swelling of her abdomen, and had never had any jaundice or "shivering attacks." She had never had any trouble with micturition or noticed anything wrong with her urine. Her bowels were open regularly every day. Her periods were normal, the last one being about a fortnight before her arrival at hospital.

Condition on examination.—The abdomen was somewhat distended in the right upper quadrant, the fullness extending from the costal margin above to the level of the umbilicus below. On palpation this distension was found to be due to a cystic swelling, spherical in shape, and about five inches *in diameter. The cyst appeared to be* movable quite freely in the abdominal cavity for about six inches in all directions It was not possible to replace the tumour into the right loin or into the pelvis. On careful palpation it appeared possible to separate it from the liver above it. On percussion it was continuous with the liver dullness above, and did not appear to be continuous with the stomach percussion note It moved with the liver on respiration. On auscultation no succussion splash was heard. Rectal examination revealed nothing. Vaginal examination showed that the cyst did not move with the cervix, when the latter was manually displaced.

Radiological report.—Before operation the patient was radiographed to determine the relation of the swelling to the alimentary tract. A barium meal of the stomach and duodenum was performed, and the report was as follows "The swelling lies laterally to the right side of the stomach and has displaced the stomach and the first part of the duodenum to the left, but not forwards or backwards The colon is also crowded up inside the left diaphragm which is displaced upwards. The stomach showed delay in emptying, whether lying or standing, but was no dilated."

Operation was performed on Jan. 26th, 1932. The abdomen was opened through a right paramedian supra-umbilica incision. A large bluish cyst was seen projecting from under the lower border of the liver, lying on the left side of the gall-bladder, and covered with the same layer o peritoneum. The falciform ligament was seen running u on to its surface, slightly to its left side. The lower surface of the liver was expanded into a thin layer enclosing th upper hemisphere of the cyst. The peritoneum was reflected from the surface of the cyst by gauze dissection, and th latter peeled off the surface of the liver. There was n connexion between the gall-bladder or any of the biliar passages and the cyst. The redundant peritoneum wa then excised, and the remnant was marsupialised by sewin it to the parietal peritoneum. The cavity was then packed *with ribbon gauze to control the slight amount* of oozin which took place, and the abdominal wound closed i layers.

Pathological report.—The cyst appears to be a simpl cyst of the liver. It contained 20 oz. of straw-coloured slightly opalescent, and somewhat syrupy fluid. The inne surface of the cyst was dull white in colour and smooth with occasional fibrous trabeculæ on its surface. On sectio the capsule was found to be composed chiefly of fibrou tissue, with occasional blood-vessels. The cyst was line on its inner surface with non-ciliated epithelium of columnar-celled type. Chemical examination of the fluid showed it to be composed of a watery medium containing albumin, cholesterol crystals, and epithelial debris, but no bile-salts or pigments.

Post-operative progress.—The patient made an uninterrupted recovery. For several days after operation the sinus in the wound discharged a small amount of slightly blood-stained serum, but this eventually ceased, the sinus closed, and she was discharged from hospital on Feb. 27th with her wound healed and sound.

A REVIEW OF PUBLISHED RECORDS.

61	Rosenstein.	M.	47	(*a*) Multiple cysts of liver and pancreas.	Recovery.
62	Payr.	F.	25	(*b*) Right lobe.	"

It is generally considered that these cases of simple non-parasitic cysts of the liver are ætiologically distinct from multiple cystic disease, in which there is frequently a coexisting cystic condition of kidneys and pancreas. Alexander[23] and Bristowe[24] also drew attention to this frequent association of multiple cystic disease of the liver and kidneys.

Incidence.—The relative incidence of simple cystic disease in other pathological conditions of the liver is small. Ackman and Rhea[25] state that only 11 cases were found among 6141 autopsies at the Montreal General Hospital during the last 24 years. Moreover, in most of these cases the condition had caused no symptoms during the life of the patient.

Table I., an analysis of 62 cases of simple cyst of the liver which came to operation, yields some interesting information. Out of this series the cyst was present in the right lobe of the liver in 20 cases and in the left lobe in 10 cases, whilst in only one case was the quadrate lobe involved. In only three cases was the cyst entirely intrahepatic. In nine of the cases it was not possible to state definitely from which lobe of the liver the cyst had taken origin, and in six other cases the cysts were multiple—occurring in both lobes. The relative frequency in the sexes in this series of cases is 46 females to 13 males, the sex in three cases not being given by the literature. This is approximately the same ratio as in Kusakabe's[10] cases, in which he found 36 females to 12 males. In four cases there was associated cholecystitis with the presence of stones in the gall-bladder or common duct, and in four cases there was cystic disease of the kidneys present also.

The cysts may give rise to symptoms at any time of life apparently, the earliest recorded case being 1½ years old and the oldest 75 years of age. But in the majority of cases the cysts do not give rise to symptoms until after 20 years of age. The age-incidence is shown in Table II., from which it is seen that the greatest incidence takes place between 40 and 60 years of age.

TABLE II

Age in years.	Number of cases.	Percentage.
0–10	3	4·8
10–20	5	8·0
20–30	10	16·1
30–40	6	9·7
40–50	13	21·0
50–60	13	21·0
60–70	5	8·0
70–80	2	3·2

Age was not given by the authors in five cases.

Mode of formation.—Simple liver cysts are usually regarded as due to retention from local obstruction of small intrahepatic bile-ducts. This group of tumours corresponds to (*e*) in Sonntag's[22] classification above. Boyd[26] suggests that they are either due to hyperplasia and secretion occurring in an aberrant extrahepatic duct, or to retention due to congenital obstruction. Waring[27] suggests that many of them are sterile hydatid cysts, and that the remainder are either dilated bile-ducts due to obstruction or to some congenital abnormality, or that they are lymphatic cysts. Bland-Sutton[28] regards them as due to pressure on an intrahepatic bile-duct, and has suggested pressure by the corset as the responsible factor. Costantini and Duboucher[29] regard them as dysembryomata, and suggest a parallel to polycystic disease. Other methods of formation have been put forward, such as rupture of an intrahepatic bile-duct (Doran[30]) and dilatation of the glands of the larger bile-ducts (Moscowitz[31]).

It is not proposed here to go into the methods of formation of the other subdivisions of Sonntag's list, most of which are obvious.

Morbid anatomy.—True simple cysts of the liver are usually single, though in a certain number of cases "daughter-cysts" may be present. They may vary in size between extremes: in Bayer's[32] and Winckler's[33] cases the cysts contained 13½ pints of fluid, and occasionally very small cysts are found post mortem. A typical cyst is usually enclosed in a firm fibrous capsule containing numerous blood-vessels, and may show calcareous degeneration in long-standing cases. It may occasionally be multilocular—Alexander[23] found five and Bevan[34] eight separate cavities. The inner wall is usually smooth, but may show fibrous trabeculæ, and is generally a dull white colour. The contents of these cysts vary considerably. They are usually clear or slightly opalescent, but may be blood-stained or bile-stained; Doran's[30] case contained 2½ pints of bile. The fluid is albuminous, and usually contains cholesterol and epithelial debris, having a specific gravity of 1007-1024 (Ackman and Rhea[25]), and is either neutral or slightly alkaline in reaction.

Microscopic appearance.—The capsule is composed of layers of fibrous tissue containing many blood-vessels and occasionally bile-ducts. The lining epithelium is usually either columnar or cubical, or may even be ciliated columnar occasionally; Zahn[35] has collected 14 such cases. In the latter instance the presence of ciliated epithelium is a strong argument in favour of the developmental origin of the cyst from the biliary ducts, since the primitive foregut (from which the liver "buds" develop) is also lined with this epithelium.

Clinical features.—Simple serous cysts seldom give rise to symptoms until they become sufficiently large to cause pressure on surrounding structures. They occasionally cause pain, probably from tension on the peritoneum. Symptoms may arise from pressure on the following structures:—

(*a*) The alimentary tract—vomiting and obstruction.
(*b*) The biliary system—jaundice.
(*c*) The portal vein and inferior vena cava—ascites and œdema of legs.
(*d*) The transverse colon—alternating diarrhœa and constipation.
(*e*) The ureters.

Occasionally they may suppurate and give rise to peritonitis, or may perforate into the abdominal cavity. Hæmorrhage may occur into a large cyst and prove fatal (Kilvington[36]).

Diagnosis is usually difficult, and very few cysts are diagnosed before operation or post mortem. Pneumo-peritoneum, with subsequent radiographic examination, has been suggested by Hoffmann[37] as a mode of diagnosis, but has not proved very successful. According to Ackman and Rhea,[25] when pain results from peritoneal pull it disappears on lying down, whilst dyspnœa is induced or exaggerated; and they suggest this as a valuable method of diagnosis. The condition may simulate cholecystitis (Ackman and Rhea[25]), ovarian cyst (Stevens[38]), or tuberculous peritonitis (Alexander[23]). The differential diagnosis is from any other cystic condition inside the abdomen, and the following conditions have to be considered: (*a*) cystic tumours of the pancreas; (*b*) cystic tumours of the kidney; (*c*) mesenteric cysts; (*d*) mucocele and pyocele of the gall-bladder; and (*e*) ovarian cyst.

Even if the tumour is successfully diagnosed as a cyst of the liver, the possibility of its being either a hydatid cyst or even an amœbic abscess must not be forgotten. In the former possibility the performance of Casoni's test may help in the diagnosis.

Treatment and prognosis.—The treatment is excision of the cyst—whole if possible—and marsupialisation of the cavity in the liver. When the cyst is entirely intrahepatic the treatment is that of amœbic abscess. Care should be taken when irrigating the fistula which results from marsupialisation of the cavity in the liver, as leakage from the track has occasionally caused peritonitis and death.

The mortality of this condition in the cases appended was 13 out of 62 cases—20·9 per cent. within six months, of which three died from post-operative shock (4·8 per cent.), and four from peritonitis (6·4 per cent.). But if the cases performed early in the last century are excluded (which were simply tapped), the mortality-rate is reduced to 16·1 per cent.—a somewhat higher mortality than that given by Schaak,[2] which was 12 per cent. in his series of cases. In cases which recover from operation a fistula from marsupialisation of the cavity always persists for a greater or less time, and in eight cases out of the 62 recorded here the sinus still persisted when the case was reported.

POINTS OF INTEREST IN THIS CASE

The case described above is a fairly typical one of simple liver cyst. The patient had not noticed any swelling of her abdomen, suggesting that the cyst had been gradually enlarging for some time. The symptoms of which she complained—viz., "pain in the right upper part of her abdomen, getting gradually worse towards the end of the day"—is the usual one which first attracts the attention of the patient.

The differential diagnosis was considered to lie between :—

A. *Cyst of the kidney.*—Against this was the absence of urinary symptoms, and the fact that the swelling could not be replaced properly into the right loin, and that there was no band of resonance separating it from the liver dullness.

B. *Cyst of the pancreas.*—Against this was the relative rarity of cysts of the head of the pancreas, and the fact that there were no signs or symptoms of biliary or pancreatic obstruction present.

C. *Mesenteric cyst.*—This was considered the most likely diagnosis. The cyst appeared to be fairly freely movable, and the absence of symptoms suggested this condition. The X ray appearances also suggested that the cyst was mesenteric in nature, rather than pancreatic.

The actual diagnosis of simple liver cyst was never even suspected, as the swelling appeared to be separate from the liver on palpation. At the operation the cause for this fact was apparent; the liver substance was very thin over the upper border of the cyst, and thus allowed the examining fingers to be dipped between it and the liver. The liver itself was also extremely movable, and had apparently been moving with the cyst on abdominal examination.

The operation and post-operative progress were normal and successful, and the pathological examination of the cyst and its contents revealed the normal state of affairs met with in this condition. The absence of bile from the contents of the cyst is explained by the fact that it usually disappears from cysts of long standing (Rolleston and McNee[39]).

In conclusion we wish to thank Mr. R. A. Ramsay for his permission to publish this case; Dr. H. C. Lucey, for the pathological reports on the cyst; and Dr. G. T. Loughborough, for the X ray examination and report.

Clinical and Laboratory Notes

TETANUS FOLLOWING IMPACTION OF A FOREIGN BODY IN THE NOSE

BY J. J. M. BROWN, M.B. EDIN.
AND
C. R. MACDONALD, M.B. EDIN.
RESIDENT MEDICAL OFFICERS, EAR, NOSE AND THROAT DEPARTMENT, ROYAL HOSPITAL FOR SICK CHILDREN, EDINBURGH

IN April, 1931, a case of tetanus was described by Dr. T. H. G. Shore in your columns[1] with a method of infection so rare that a similar case is worthy of record.

A boy, aged 4, was admitted to the Royal Edinburgh Hospital for Sick Children on May 4th last, with the complaint that he had been unwilling to open his mouth for 12 hours.

History.—Seven days previously, while playing in the street, he had inserted a bead into his left nostril. The family doctor, consulted several hours later, saw the bead lying far back on the floor of the nasal cavity, wedged between the nasal septum and the left inferior concha, but owing to the patient's struggles it was not possible to remove the bead, which slipped from the forceps. Rhinoscopy now failed to reveal the foreign body, but there was a clear airway on the left side, so the doctor concluded that the bead had passed into the nasopharynx and had been swallowed. Next day the boy was perfectly well, and remained so until the morning of the day of admission, when he refused to open his mouth to take his breakfast. Twelve hours later he was admitted to hospital.

On *admission* he resented examination, and answered questions with his jaw clenched. From the parents we learnt that the bead had never been discovered, in spite of careful examination of the stools. *Anterior rhinoscopy* was inconclusive, although there was a small elevation far back on the floor of the nose, which might have been a foreign body. The boy was asked to open his mouth, but refused or was unable to do so. As soon as a spatula was inserted between his teeth he went into a state of generalised tonic spasm, which was typically tetanic. The breathing was stertorous, the face cyanosed, the neck and arms rigid, the hands clenched, and the back arched, and the lower limbs, although hypertonic, did not show such marked rigidity. A minute later the spasm passed off as quickly as it had begun. It was then noticed that he had slight left-sided facial paresis and risus sardonicus. His temperature was 101·8° F., and his pulse-rate 148.

---

[1] THE LANCET, 1931, i., 916.

Under local anæsthesia a further examination of the nose was carried out, and the object previously mentioned, which proved to be the bead, was removed. It was an ordinary paste bead with a rough surface, and was carefully preserved for bacteriological investigation.

Treatment, following a recent paper by L. B. Cole,[2] consisted in administering massive doses of tetanus antitoxin. Under general anæsthesia lumbar puncture was carried out, and 25 c.cm. of cerebro-spinal fluid was withdrawn. The fluid was under pressure, and on examination both chemically and microscopically was found to be normal in all respects. It was replaced by 50,000 units of antitetanic serum, and a further 50,000 units was injected intravenously.

On recovering from the anæsthetic the child was in exactly the same state as before. When raised by the occiput his back remained rigid, flexion occurring at the hips. During the night he had two short spasms, each of a few seconds' duration, and characterised by generalised clonic twitching. Next day his condition was unchanged, although his temperature had fallen, and in spite of the administration of large quantities of glucose, there was acetone in both breath and urine. He was given a further 26,000 units of antitetanic serum by the intravenous route. His temperature rose again that night to 102·8° F., and at 8 A.M. next morning he became unconscious. The rigidity was still very marked. He never regained consciousness and died at 10.15 A.M.

A *post-mortem examination* was performed, the positive findings being as follows: (1) The left middle-ear cleft contained mucopus; (2) there was a well-marked purulent exudate, suggestive of leptomeningitis on the lateral aspects of both cerebral hemispheres, especially on the right side, and in the walls of the longitudinal fissure. There was no basal meningitis.

Bacteriologically the meningeal exudate was sterile. Cultures were made from the bead and from the floor of the nose, and from the only other possible source of infection, a small abrasion on the right wrist. The cultures from nose and wrist showed no organisms resembling *Bacillus tetani*, but the culture from the bead showed organisms resembling *B. tetani*, along with other organisms. Subculture was performed on two occasions, and the drumstick bacilli were isolated in almost pure culture.

The points of interest in this case are: (1) The unusual method of introduction of the infection. (2) The rare combination of facial paresis and tetanus (*Kopftetanus*). (3) The failure of even massive doses of antitetanic serum in checking the progress of the disease. (4) It raises the question of the advisability of administering antitetanic serum as a prophylactic in similar cases where the foreign body may have been infected with tetanus spores or bacilli.

We are indebted to Dr. Douglas Guthrie, aural surgeon to the hospital, for allowing us to publish the case.

THE BLUE ("MONGOLIAN") SPOT

AMONG JEWISH GROUPS IN PALESTINE

BY HELEN KAGAN, M.D.

PHYSICIAN-IN-CHARGE OF THE CHILDREN'S SECTION OF THE SHAARE ZEDEK HOSPITAL, JERUSALEM

THE so-called "Mongolian" spot is a blue, flat spot in the sacral or dorsal region which gradually fades away into the normal colour of the skin; it is congenital and disappears at the end of the first or second year of life without leaving any trace. It was first observed by Erwin Baelz (1885) in new-born Japanese infants, and received its name from him. A few years later it was established that the spot existed among all Mongolian peoples. Among the white races it is seen only in exceptional and isolated cases, but it has long been known to the people in regions inhabited by negroes, and in countries like Peru and the Argentine it is considered a sure sign of negro blood. Its incidence among negroes and the offspring of intermarriage between them and other races conclusively proves that the so-called Mongolian spot cannot be regarded as a Mongolian racial characteristic, and it should therefore be called simply the "congenital blue spot" (macula cœrulea congenita).

B. Adachi[1] showed that the identical corium pigment cells that cause the blue spot were to be found in the corium of the sacral region in 50 per cent. of all new-born infants of the Caucasian race. He was able to prove that the pigment of the epidermis and that of the corium are, embryologically, formed independently of each other. He also pointed out that the presence of pigment in varying degree, at times in the epidermis, at times in the corium, forms an outstanding characteristic of different types of ape. The chimpanzee, for instance, possesses extremely little corium pigment and a large quantity of epidermal pigment, which is responsible for the brown colour. The opposite is the case with the macaque, which possesses very little epiderma pigment and a large quantity of corium pigment and is of a blue colour. In man the epidermal pigmen alone remains, while the corium pigment, mos frequently localised in the sacral region, is preserved in a very rudimentary and transitory form during the last months of intra-uterine life and the first year It may remain in microscopical quantities in the Caucasian race, or in larger quantities causing the blue spot.

The blue spot cannot be regarded as directly proportional to the degree of general pigmentation of race or individual, though there is a close inter relation between its existence and the intensity o the epidermal pigmentation of the body. In Palestine I have found several pronounced blue spots in children with a very fair skin, brown hair, and brown eye (though never in children with fair skin and blue eyes) while not infrequently children with dark skin and dark brown hair and eyes, contrary to all expectations showed no trace of it.

The blue spot can at times furnish a clue t parentage. Thus in the case of a child with very fair skin, chestnut hair, and grey eyes, a large blu spot in the sacral region, and a fair Anglo-Saxon father, we assumed some admixture of exotic blood and subsequent inquiries showed that the mothe was a Syrian. A younger sister, fair and with blu eyes, showed no trace of the blue spot. According to Adachi's conception, the blue spot would still remain a symptom of anthropological importanc which should not be under-estimated.

A SYSTEMATIC STUDY IN PALESTINE

No special investigations with regard to th incidence of the blue spot among the Jews of Europ and America seem to have been made. This fac may imply that the incidence of the blue spot i not much more frequent in Jews than in the people among whom they have long been living, a deduction that seems to be corroborated by our own observation among the Ashkenasic and other Jewish groups. My attention was first drawn to the existence of the blue spot in the infant welfare centre in the Jewish quarter of the old city, the first of its kind in Jerusalem, attended at that time by many Yemenite children from the Shiloah village. The blue spot there was very common, whilst at the Rothschild Hospital, attended mostly by Ashkenasim, only the most diligent search led to its detection.

---

[2] Brit. Med. Jour., 1932, i., 743.

[1] Zeit. f. Morph. and Anthrop., 1903, iv., 1.

My investigations were conducted between 1921 and 1924 on 2663 Jewish infants up to 12 months of age who passed through my hands in my capacity of physician-in-charge of the children's section of the Rothschild Hospital and the Hadassah infant welfare work in Jerusalem.

Origin of parents.	Cases examined.	Positive.	Negative.	Per cent.
Ashkenasim—				
Poland, Russia ..	1419	6	1413	
Hungary	106	—	106	
Germany	68	1	67	
Rumania	92	1	91	
	1685	8	1677	0·47
Sephardim	620	15	605	2·41
Georgians	23	5	18	21·7
Bokharians	26	9	17	34·6
Mugrabi (N. Africa)..	52	28	24	53·8
Aleppo	29	19	10	65·5
Persians	116	100	16	86·2
Yemenites	112	101	11	90·1

The Table shows that the origin of the parents or infants plays a very important rôle. Thus the children of the so-called Ashkenasic parents, hailing from Poland, Russia, and Hungary, showed a frequency of 0·47 per cent., whilst those of Yemenite parentage showed a frequency of 90 per cent., an incidence 180 times as great. Offspring of marriage between Ashkenasim and Yemenite Jews show a heavy incidence.

The blue spot is comparatively rare among the Sephardim (Spanish Jews), its incidence being only five times as great as among the Ashkenasim. Most striking, however, is the increased frequency in Jews from Asia and North Africa—i.e., Georgian, Bokharian, Persian, and Yemenite. Without in any way wishing to stress the significance of the blue spot as a racial characteristic, it is certainly striking that the Ashkenasim, followed closely by the Sephardim, show so markedly low an incidence as compared with the Asiatic groups. It would be most interesting if a study could be made in regions inhabited by Sephardim in homogeneous masses where no opportunity offers for intermarriage with Asiatic Jewish groups. A proper understanding of the laws of heredity governing the incidence of the blue spot will only be attained after systematic research extending over decades, including the examination of all new-born infants of the various Jewish groups, and when the descendants of individuals affected with the blue spot in infancy can be definitely traced.

In the course of the *past* 40 years the Jewish race has been widely discussed from every possible aspect and angle, and all kinds of conflicting opinions have been expressed with regard to the existing or entire absence of purity and unity of race of the various groups. It is certainly not my intention to attempt to draw any conclusions concerning the purity of the Jewish race from the frequency or infrequency of the blue spot, but the observation made so far will no doubt be of interest to all those engaged in anthropological studies of the Jewish race and its various groups.

CONCLUSIONS

1. The blue spot has anthropological significance.
2. The incidence of the blue spot among Jews varies according to their origin. It is rarest (0·47 per cent.) in the Ashkenasic Jews hailing from Poland, Russia, and Hungary, and most frequent (90·1 per cent.) in Jews from the Yemen.
3. Among the Spanish Jews in Palestine the incidence of the blue spot is five times as high as among the Ashkenasim, though considerably lower than among the Jews belonging to the Asiatic and North African groups.

PRIMARY THROMBOSIS OF THE AXILLARY VEIN

WITH RECURRENCE

By Douglas Firth, M.D. Camb., F.R.C.P. Lond.
PHYSICIAN TO KING'S COLLEGE HOSPITAL
AND
Roderick Mackay, M.B. Aberd.

In November, 1930, a healthy girl of 19 was attending a school of domestic economy and during the course of her work stirred a heavy Christmas pudding mixture. On the following morning the right arm ached, and in two or three hours the arm and forearm became much swollen and of a deep pink colour; three days later there was definite discomfort and fullness of the axilla. She was seen next day by one of us (R. M.), who found general œdema of the hand and arm, and a swelling, the size of an almond, in the axilla.

When seen on Nov. 16th the right arm was swollen, cyanotic, and pitted on pressure. It was warm, and the radial pulse was easily found. The axilla felt full, but no glands were detected, and while movements of the limb caused discomfort there was no pain in the joint. No fever was detected at any time. A general clinical examination revealed no other abnormality, and a radiogram of the shoulder showed bone, joint, and periosteum to be normal.

The swelling subsided very slowly, but had entirely disappeared in five months, by which time the full use of the arm had been restored, although it ached a little after a heavy day. The girl remained very well until June 23rd, 1932, when the *left* arm ached and began to swell. This was more noticeable on the 26th, and in a few hours the condition of the left arm resembled that of the right 19 months previously. It was œdematous from shoulder to fingers, slightly blue, with prominent veins. There was no history of previous trauma or undue exertion. On the 30th the left arm was swollen to the shoulder, pitted on pressure, and a little cyanosed. The axilla was full, but nothing definite was palpable and no tenderness was detected anywhere. As before, the rest of the examination was negative. No septic foci were found, and indeed the girl seemed to be, as she always had been, in excellent health.

A complete blood examination was carried out, and as we have seen no record of such examinations the figures are appended.

Red cells	5,440,000	Polymorphs.	71·0 %
White cells.. ..	7,600	Eosinophils	0·5 %
Hæmoglobin ..	103 %	Lymphocytes	27·0 %
Colour-index ..	*0·95*	*Large hyal. mono.* ..	1·5 %

Platelets: 330,000 per c.mm. (normal 200–500,000). *Coagulation time:* 1 min. 41½ sec. (Dale and Laidlaw's method). *Blood calcium:* 11·2 mg. per 100 c.cm. (normal 9–11 mg. per 100 c.cm.).

The swelling of the arm began to decrease after a fortnight, and the colour is now normal with every prospect of complete restoration of the full use of the limb at no distant date.

Primary thrombosis of the axillary vein, of which the above is a typical instance, is a rare though recognised condition which has attracted more attention on the continent than in this country, where the most recent paper appears to be that of

Pearce Gould and Patey[1] in 1928, who recorded eight cases, and gave a full summary of the literature from which certain definite points emerge.

The condition affects mainly young adults between 20 and 30 years of age; the sex in nearly all cases is male, and the arm affected the right. Usually a history of trauma, in the shape of unusual exertion or use of the arm, can be obtained, and most authorities agree to the view that trauma is a definite factor in the ætiology.

Pearce Gould and Patey, and Lowenstein (whom they quote) conducted experiments to ascertain the structure responsible for the trauma, and while the latter suggested the costocoracoid ligament damaged the axillary vein, the former considered the subclavius muscle is responsible for trauma to the delicate subclavio-axillary valve; in both cases undue "exercise" with the arm abducted and the vein distended by an expiratory effort being necessary factors.

Löhr,[2] who describes six cases, and points out that the condition has nothing to do with ordinary thrombosis of the upper extremities, agrees to the principle if not to the actual cause.

The diagnosis is easy if the condition is kept in mind and the progress good, the only treatment needed being rest and later massage.

The case described presents some added features of interest: the sex is unusual, the involvement of the opposite side after an interval of time has not apparently been recorded before, while the uniformly negative results obtained on clinical and pathological examination strongly support the hypothesis that trauma, and trauma alone, is the primary cause of the condition.

BRITISH MEDICAL ASSOCIATION

CENTENARY MEETING IN LONDON

SECTION OF OTO-LARYNGOLOGY

UNDER the presidency of Sir STCLAIR THOMSON, this section discussed the end-results of the

Tonsil and Adenoid Operation

in childhood and adolescence. The subject was introduced from the statistical standpoint by Dr. J. ALISON GLOVER (London) in a paper by himself and Dr. Joyce Wilson. He explained that by "tonsillectomy" he meant the double operation, and by "end-results" the result seen after convalescence from the operation was complete. In 1923 when a number of warnings on the subject were issued by the chief medical officer of the Board of Education it was found that 47,685 such operations had been carried out in England and Wales, while in 1930 the number had risen to 109,738. The operation was particularly rife in public schools, where the percentage of the boys who had had tonsillectomy done varied from 33 to about 70. And more cases *than ever were now being operated* upon at 6 years of age. In Munich only one-half per cent. of the school-children were tonsillectomised, and in Missouri State only two per cent. Enlarged tonsils and adenoids affected all classes of the community about equally, yet a disproportionately large number of children of the more leisured classes suffered the operation. It was therefore well to pause and reckon up the end-results of this growing practice. There were, he said, three classes of patients to consider: (1) those in whom it was certain that the tonsils were diseased; (2) those in whom there was reasonable doubt as to this; (3) those in whom tonsillectomy was done as a preventive or curative measure. W. M. Ash, in an analysis of 1691 cases, showed that out of 100 cases 20 were operated on for frequent sore-throats and tonsillitis, 12 for frequent colds, 12 for chest conditions, 11 for enlarged turbinates, 11 for earache and obstructive deafness, 4 for tubal catarrh, 6 for otitis media, 6 for enlarged cervical glands, 4 for rheumatic conditions, 9 for systemic and general conditions, 3 for eye conditions, 4 for what were called reflex conditions. An extensive statistical inquiry did not support the contention that tonsillectomy was a safeguard against subsequent illness due to infectious disease. He held no brief for the retention of diseased or really obstructive tonsils or adenoids, nor did he cast doubt on the high value of the operation in cases in which there was sure evidence of toxic or obstructive damage; but a review of the literature suggested that the excellent end-results of tonsillectomy in selected cases had been statistically overweighted by the indifferent end-results in cases in which the operation had been performed as a prophylactic ritual. A large proportion of the tonsillectomies now being done on children were, he thought, unnecessary.

DISCUSSION

Dr. REGINALD MILLER (London) said the cardinal feature of rheumatism in young subjects was twofold: (1) its tendency to recrudesce and relapse; (2) the danger of damage to the heart valves, a condition responsible for so many deaths in young and middle-aged people. In these rheumatic subjects the throat was not grossly obstructed; frequently the tonsil was small, and in a number of the cases it was buried. Some 80 per cent. of rheumatic children had septic tonsils and suffered from sore-throats before actual rheumatic symptoms developed. The rheumatic attack was often ushered in by tonsillitis and the association between rheumatism and tonsillitis was very close. It was difficult to assess the *value of tonsillectomy, as the problem* was so complicated; no statistics could take the place of the impression to be derived from a careful watching of the cases over a considerable period. His practice was to keep these children on definite doses of salicylates. Many of his cases certainly had been spared serious rheumatic trouble by tonsillectomy. His view was that early tonsillectomy lessened the danger of fresh trouble in the heart, and if there should be another rheumatic visitation its intensity was much reduced by the operation. Though the tonsils were the main portal of entry of the causa microbe, they were not the only one; certainly the intestines were another portal, and the environment was important. He contended that there was no reason to be dissatisfied with the results of tonsillectomy when it was performed under proper safeguards.

Mr. J. A. KEEN (Leicester) thought it was fair to draw conclusions from efficiently performed tonsillectomies; a second operation for removal of tonsils ought never to be needed. An imperfectly performed operation was worse than no operation, and the tendency to colds and other troubles was then worse than if nothing had been done. Sometimes the operation was blamed for a result due to nothing but faulty technique. He did not agree that a high-arched palate was a result of neglected adenoids. In assessing end-results, the condition many months after the operation should be considered. He was able to show a distinct increase in all the measurements of children after the operation.

Mr. James Adam (Glasgow) thought that not sufficient attention was directed, generally, to measures to avoid the need for operation. Lymphoid tissue would not be present unless it served a purpose in the body economy. If, as Dr. Miller contended, it was so important to remove the tonsils for rheumatism, why was not the lingual tonsil included? In a series of 100 operated children compared with another of 300 not operated it was found that less infectious disease was caught by the non-operated than by the operated. The ideal age for removal was 6 to 7 years; if it were done at a later age, the adenoid facies resulted.

Mr. A. Lowndes Yates (London) remarked that when small pieces of tonsil were left behind at operation, they did little harm until the fibrous tissue contracted; then in later life there ensued a scarring on fauces and palate. To leave such portions was not as harmless as some thought. An operation for this condition was only half performed if all the conditions present were not dealt with; sepsis might be a constant factor, because of the daily environment of the patient; even septic teeth in the mouth of the mother might be a real danger to her child. In these cases too there was usually some coexisting sinusitis and rhinitis. In some patients the resistance was so low that operation should be postponed until it had been raised. It did not always follow that because tonsils were enlarged they should be removed.

Mr. C. Hamblen Thomas (London) agreed that tonsil and adenoid operations were now definitely on the increase, and in some instances the practice was excessive. In some, the fact of operating was a confession of failure. It could be accepted, in a general way, that the reason a physician sent a child for the operation was that his observation had taught him it was beneficial; certainly parents who brought their children to have the operation done held that view, and they were unprejudiced witnesses. Removal of diseased tonsils and adenoids increased the child's alertness, although no improvement could be expected in the mentality of defectives.

Mr. C. E. Jones-Phillipson (Cape Town) said there would always be many who would continue their practice of removing diseased tonsils and adenoids because they were convinced of the good end-results. These results however were not so good as they might be if sufficient attention was paid to the teeth.

Dr. Dan McKenzie (London) said the fact that a recurrence of lymphoid tissue took place after operation played havoc with the value of the statistics presented in the opening paper. It was important to know whether, in the figures quoted, examination was made for the presence of adenoids of the nasopharynx; without that, the statistics were of little value. What was required was information as to the causal factors in these enlargements.

Dr. J. Kerr Love (Glasgow) protested that tonsil and adenoid removal should not always be linked together, as was the present practice. He pleaded for earlier removal of adenoids, leaving the tonsils until it was seen whether they actually produced harm.

Dr. P. Watson-Williams (Bristol) reminded the meeting that it was at his instigation that the Royal Society of Medicine instituted an inquiry into the frequency of the operation. So long as the tonsils were able to cope with the infection they could be left, but when they became choked by a massive infection, removal of them was justified. Not until it was felt that the patient had a systemic infection should the tonsils be removed.

The President said that the surgeon should be first a physician, searching for all possible sources of trouble before deciding as to operation. It could be said that few had left tonsils which they should have removed, but many removed tonsils which they ought not to have removed.

SECTION OF NEUROLOGY

With Dr. J. S. Collier, a vice-president of the section, in the chair, a discussion on

Disorders of the Sympathetic Nervous System

and their response to medical and surgical treatment was opened by Prof. Edwin Bramwell (Edinburgh). The sympathetic nervous system was, he said, occupying an increasingly prominent position in medicine, and he proceeded briefly to review the progress of neurology since the time of Sir Charles Bell's work in 1811. The attention of clinicians during the first half of the nineteenth century had been mainly directed to the problems of the correlation of symptomatology with morbid anatomy, the differentiation of diseases, and the significance of physical signs. Shortly afterwards further additions to neurological knowledge were made by the histological work of Golgi, Nissl, and others. As the nineteenth century drew to its close, physiological conceptions tended to replace the more strictly anatomical outlook, especially owing to the work of Hughlings Jackson and Sir Charles Sherrington. Finally, an impetus was given to the psychological aspect of nervous disease by the studies of Janet, Dejerine, and Freud. Up to the last few years little attention had been paid by the clinician to the autonomic nervous system. Half a century ago nothing was known concerning the physiological anatomy of the autonomic system or of its purpose as a functioning mechanism. In spite of considerable progress during recent years our pathological and clinical knowledge concerning this system was still in its infancy. It was, he said, the Cambridge physiologists Gaskell, Langley, and Anderson who unravelled the scheme of the efferent autonomic system. Gaskell demonstrated that the viscera received nerve-fibres not only from the thoracic region of the spinal cord but also from the brain stem and sacral regions; he argued that the action of these two sets of fibres was antagonistic, the former probably having a katabolic, the latter an anabolic function. Langley had established the general anatomical plan of the efferent autonomic system as we now knew it; he also demonstrated that adrenaline had a stimulating effect upon the sympathetic system, and in conjunction with Anderson did much to elaborate the details of autonomic innervation. There had been some confusion regarding nomenclature, and a uniform terminology was much to be desired. The nomenclature here employed was that of Langley, who suggested the term "autonomic" to denote the system as a whole, and the terms "sympathetic" and "parasympathetic" for the thoracic and craniosacral subdivisions respectively.

It was not, said Prof. Bramwell, until the publications of Eppinger and Hess in 1909 on vagotonia and sympatheticotonia and of Crile and Cannon in 1915 on the effect of emotion that the interest of clinicians was aroused and directed to autonomic disorders. In 1924 the results of Hunter's suggestive investigations upon the dual innervation of muscle and the question of muscle tone together with Royle's operative experiences attracted the attention of surgeons. We were still, however, without definite knowledge of the morbid anatomy of the autonomic system. The condition known as achalasia gastrica (cardiospasm) was the only disease in which it had been worked out.

Sir **PERCY SARGENT** (London) stated that three main points in the surgery of the autonomic system had to be considered: (1) So far the operations were destructive, and consisted in the cutting off of sympathetic nerve-supply; as yet nothing constructive had been attempted. (2) Actual diseased structures were not dealt with so much as disturbing nervous influence resulting in disease in other parts. (3) The surgery of the autonomic system was still in an experimental stage. He then referred to resections of sympathetic nerve-roots in the treatment of Raynaud's disease and of peri-arterial sympathetic fibres in causalgia and in senile gangrene. The operation in Raynaud's disease and in Hirschsprung's disease now had an established position, and the results appeared extremely promising. Certain types of chronic constipation were amenable to similar treatment.

Mr. R. H. **BOGGON** (London) considered the treatment of chronic constipation by operative measures on the autonomic system. The colon, he said, was a complicated neuromuscular mechanism, not a simple tube. The normal functioning of this mechanism depended upon the governing factors working on a coördinated basis. He described the autonomic nerve-supply to the colon, and emphasised the fact that its normal function depended upon a proper sympathetic and parasympathetic balance. The sympathetic fibres were inhibitory and caused contraction of the sphincter and relaxation of the muscle wall, whereas the parasympathetic impulses were motor in function. Excellent results had been obtained by section of the sympathetic supply to the distal colon in cases of Hirschsprung's disease, a condition which appeared to result from lack of balance between sympathetic and parasympathetic systems. The same procedure could be applied to certain types of chronic constipation. The results were not so dramatic as in the case of megacolon, and the patients required careful after-treatment to re-educate their colons. Mr. Boggon then described the technical details of the operation, giving illustrative examples.

Prof. E. D. **TELFORD** (Manchester) referred to certain vascular disturbances of the extremities and their relation to the sympathetic nervous system. In conjunction with Prof. J. S. B. Stopford he had studied over 100 cases, in 35 of which operations had been done on the sympathetic nervous system. Six of the cases were examples of the vascular complications of cervical rib; the remainder were instances of thrombo-angeitis obliterans and of Raynaud's disease. It was not easy to differentiate between these two latter diseases; it appeared likely that they both had a common origin in some irritative lesion of the sympathetic nervous system. It was not unusual to find in the same patient classical thrombo-angeitis obliterans in the legs and a Raynaud syndrome in the hands. Of these vasospastic diseases the cases with cervical rib gave the clearest picture of vasospasm, since they arose from a chronic, persistent, and low-grade irritation of a bundle of fibres due to friction against the rib. A period of coldness and pallor due to persistent vasoconstriction was followed by the onset of thrombosis which might spread rapidly from the digits to the junction of the brachial and axillary arteries. This thrombosis was the direct result of spasm and was no doubt due to narrowing or obliteration of the vasa vasorum.

Similarly, in the other vasospastic diseases the initial spasm was followed later by thrombosis and the area of spasm was steadily diminished by the spread of a thrombotic area. Hence, if sympathectomy is to be of any use it must be done early, since although it could abolish spasm, it could have no effect on an organised thrombus. Sympathectomy appeared, in the present state of our knowledge, to be the only rational method of treatment. It should take the form of an extensive resection of cord and ganglia. The perivascular operation was anatomically unsound in the limbs, and ramisectomy, whilst ideal, was likely to prove insufficient owing to the very variable anatomy of the sympathetic nervous system. In discussing results, it was often objected that the effects of the operation were temporary. In the speaker's opinion the results were complete and permanent provided a sufficiently wide operation *had been planned on true anatomical lines. Restoration* of function depended mainly upon early operation. The later cases with severe claudication or gangrene did not do well. Every case should be tested before operation either by the induction of fever or preferably by nerve block.

Mr. **GEOFFREY JEFFERSON** (Manchester) discussed the central cell stations in the hypothalamus. He described the anatomy of and the recent work on this region of the brain in the attempted localisation of the function of the different nuclei. One of the most striking translations that neurology had witnessed was the slow stripping of one vital function after another from the pituitary body and their re-establishment in neighbouring neural structures. The metabolism of water and of carbohydrates, the regulation of blood pressure, of cardiac rhythm as well as of gastro-intestinal secretion were known to be influenced, i not directly controlled, by centres in the hypothalamus. Mr. Jefferson then described cases o cerebral tumour involving the hypothalamus, the pituitary body, and the third ventricle. Such lesions might be associated with glycosuria, disturbance of temperature, polyuria, polydipsia, &c.—and h illustrated his descriptions with lantern slides. Fo too long, he concluded, we had regarded man as a spinal and medullary animal when we had attempted to explain sudden and unexpected fatalities. I this view were true it should be almost impossible to die from a hemispherical lesion; but actual experience completely refuted such a belief. In th explanation of fatalities from hemispherical lesions a supratentorial cause must be looked for as we as a possible medullary involvement. It was i the head ganglion of the sympathetic in the midbrai that we should seek for the explanation of thes occurrences.

Prof. J. **BEATTIE** (Montreal) described the anatomy and physiology of the hypothalamic region. Ther were three main groups of nerve-cells: (1) the supra-optic; (2) the posterior hypothalamic; and (3) th posterior pituitary. The posterior hypothalami group controlled mainly the autonomic system an when this group was destroyed in animals the invariably died from general peritonitis followin perforation of acute gastric or duodenal ulcers The hypothalamic group of cells, he considered maintained the balance between the sympathetic an the parasympathetic systems. The supra-optic nucl inhibited and possibly controlled to some exten the hypothalamic group. The connexions and physiological mechanisms of the different hypothalamic nuclei were then described and illustrated with diagrams.

Dr. W. Russell Brain (London) described the anatomical arrangements, both central and peripheral, of the ocular sympathetic system and detailed the clinical phenomena resulting from its disturbance. Exophthalmus might occur as the result of organic lesions of the central nervous system, such as encephalitis lethargica, cerebral vascular lesions (especially when situated in the choroido-occipital region), tabes dorsalis, and rarely in disseminated sclerosis and in hereditary ataxia. Penfield had described it as part of the attack in what he had termed "diencephalic autonomic epilepsy"—a widespread excitation of autonomic function which occurred paroxysmally in a case of tumour of the third ventricle. Exophthalmus, especially retraction of the upper lid, resulted from over-action of the ocular sympathetic system. Thus, there were at least two factors responsible for the production of exophthalmus: (1) over-activity of the ocular sympathetic system, and (2) œdema of the orbital contents. Vasodilatation of central origin might also play some part in its production and this aspect might well repay further investigation.

Mr. A. S. Blundell Bankart (London) commented upon the fact that little had been said about sympathectomy for spastic paralysis. The reason of course was that this method of treatment, based he believed on an unsound physiological research, had proved a failure in practice and was now discarded. It should not be forgotten, however, that all recent work on the surgery of the sympathetic nervous system was the outcome of earlier attempts to influence the tone or spasticity of skeletal muscles by removing their supposed sympathetic nerve-supply. Although these earlier operations failed to accomplish their purpose they might have some value. Mr. Bankart had a special interest in the subject as he believed he was the first surgeon to perform sympathectomy for spastic paralysis in the human subject, and incidentally the first to employ the posterior approach to the sympathetic ganglia and cord. Removal of the stellate ganglion for infantile hemiplegia did not have any effect upon the tone or spasticity of the muscles, nor so far as could be seen upon the circulation of the limb. Although there was some transient vasodilatation, there was no obvious lasting change and no disturbance of the sympathetic nervous system was found even when a patient was seen years afterwards, beyond a slight degree of enophthalmus. The operation of ramisectomy as devised and employed for the express purpose of alleviating spastic paralysis had proved a complete failure. Incidentally, however, it gave us a technique which opened up possibilities of treating other conditions which might be benefited by a more or less permanent sympathetic paralysis.

Mr. J. Bagot Oldham (Liverpool) described the use of spinal anæsthesia as a test of the results that might be expected by sympathectomy, especially in cases of intestinal stasis and in Hirschsprung's disease. In the latter, the colon on X ray examination was found to be relatively contracted during spinal anæsthesia; the same result could be expected from sympathectomy. He mentioned that after four years two cases of Hirschsprung's disease remained perfect clinical examples. Renal sympathectomy had been found to abolish renal pain and he mentioned four cases which had been relieved by such an operation.

Dr. S. Levy Simpson (London) said that some 70 years ago Raynaud described his disease and put forward his theory of a vasomotor neurosis. In 1929 Sir Thomas Lewis carried out an interesting series of experiments and concluded that we must discard Raynaud's theory and substitute for it the hypothesis of a local fault of the digital vessels. Working with Brown and Adson at the Mayo Clinic over a long period, Dr. Simpson had found that Lewis's views were applicable only to late complicated cases of the disease in which secondary changes had taken place in the terminal digital vessels. In early cases, anæsthetisation or complete interruption of the sympathetic nerve-fibres by operation prevented any manifestations of Raynaud's disease. He would also emphasise the attacks produced by psychic stimuli. These attacks were often associated with sweating of the hands, and if one did not admit a hypersensitivity of the sympathetic nervous system it would be necessary to postulate an abnormality of the sweat glands for which there was no evidence. White of Boston had since carried out similar observations and had confirmed the work at the Mayo Clinic. It was therefore a matter of regret that Sir Thomas Lewis had not referred to this aspect of the problem in his recent lecture. Dr. Simpson did not agree with Prof. Telford's attempt to identify Raynaud's disease with thrombo-angeitis obliterans. The invariable symmetry, the patency of the vessels at the wrist or ankle, the age, and sex, were some of the features that distinguished Raynaud's disease.

SECTION OF RADIOLOGY

At the first meeting of this section the chair was taken by the President, Dr. Stanley Melville, and Dr. J. F. Brailsford (Birmingham) opened a discussion on the radiographic investigation of

Lumbar and Sciatic Pain

He said that no group of symptoms might be due to such a diversity of causes as those known as "lumbago" or "sciatica." It was possible to determine the cause of the symptoms by radiography in a large number of cases, and no wise clinician would neglect this aid. The lesions causing the symptoms might be due to (*a*) congenital or developmental abnormalities; (*b*) trauma; (*c*) toxæmia; (*d*) acute or inflammatory conditions; and (*e*) tumours.

Congenital or developmental abnormalities occurred in a comparatively large percentage of apparently normal people. They should not be taken as the cause of the symptoms without good reason, but operation to cure them often relieved the pain. "Gynæcological" backache could often be elucidated by radiography. Injuries to the back seemed to be far more important in middle life than in youth; many attacks of so-called lumbago seemed to originate in sudden involuntary movements of the spine. It was difficult to assess the importance of trauma and pain, but where a claim to compensation might arise it was essential to take a radiogram as soon as possible and to examine it very carefully for bone injury. Immediately after injury to a vertebral body there might be very little evidence of deformity, but a week or so later signs of crushing might be visible.

In particular patients relief might be obtained by the discovery and eradication of any one or several of the various septic foci, but no such success should be allowed to become an obsession and a thorough investigation should be made before conclusions were drawn. No more characteristic lesion was detected by radiography than dental sepsis; and no more clearly related examples of cause and effect could be found. Unfortunately, the patient was often unaware of his dental trouble and often his dentist was not consulted when the symptoms arose. If the teeth gave the patient no discomfort and showed no clinical or radiographic signs of sepsis, they were not the cause of symptoms. In Dr. Brailsford's view the dental radiograph should be taken and interpreted by a radiologist; it was important to radiograph the site of pain as well as the possible source of toxin. Only harm could be caused by the removal of normal structures. In lumbar and sciatic pain, antero-posterior and lateral radiograms of the lumbar and sacral spine, pelvis, and hip-joints should always be made. Paget's disease and secondary malignant deposits might be discovered radiographically before there was any clinical evidence of their existence.

Dr. R. M. **Beath** (Belfast) said that the pain of urinary disorder varied from frequent attacks of acute renal colic to a dull, continual backache, and its intensity did not necessarily correspond with the severity of the lesion. It might follow the typical renal colic distribution; it might be unilateral or bilateral; it might radiate down the legs to the toes, suggesting sciatica, or it might be referred to the other side. Fullerton held that the distension of a renal pelvis set up impulses which might be referred to any part of the area supplied by the nerves arising from the sixth dorsal to the third lumbar. The value of radiological findings had been much increased by retrograde pyelography. With Prof. A. Fullerton he had found that intravenous pyelography was especially valuable where the passage of a cystoscope was difficult or impossible; it enabled pyelograms of both kidneys to be obtained in one examination, provided a functional test of the relative excretive activity of the two kidneys, and might give a complete diagnosis in the preliminary examination. When this method was used the patient was saved from the discomfort of the cystoscope. On the other hand, the shadows of the dye were ch less dense and well-defined than with the ograde method, and small deformities of outline ht be overlooked; moreover, since the secretion of the diseased kidney was diminished or absent, the pelvis was less well-defined. Uroselectan B was the best contrast solution for intravenous and abrodil for retrograde work.

Calculus caused pain in every variety of site and intensity without reference to its position. The pain of tuberculous kidney occurred in only about 50 per cent. of cases; it was not very severe, but took the form of a constant ache or soreness. Patients with advanced cases might have no pain, as the disease might extend gradually. The pain of renal tumour was often a dull backache. It might also be associated with cystic kidney, congenital abnormalities, and new growths of the bladder.

Dr. H. K. **Graham Hodgson** (London) dealt with the examination of the accessory nasal sinuses. He maintained that it was necessary to take radiograms from standard angles for every patient, to take several views from different angles, and to centre and angulate the tube exactly. The three positions mentioned in text-books did not permit of accurate visualisation; the erect posture was necessary. He showed a photograph of an apparatus, in which the tube could be worked at any angle or level; the head clamp could be rotated to any angle and was read off on a gauge. A common source of error was in the comparison of an opaque sinus with its fellow. The radiologist could only obtain knowledge of the normal appearance of a sinus by studying radiograms taken in standard positions. Dr. Graham Hodgson described in detail the standard views he was accustomed to use and some of the appearances of infected sinuses.

Dr. R. S. **Paterson** (Manchester) enumerated the following posible causes arising from the alimentary tract of lumbar and sacral pain: gastric ulcer of the posterior wall, especially when adherent to the pancreas; gastric carcinoma, with or without pancreatic adhesions; gall-bladder disease, especially with obstruction of the cystic duct; visceroptosis, appendicitis, and diseases of the large bowel. The clinician should localise the lesion before referring the case to the radiologist, but the latter should not neglect an enema examination even if he found an adherent ulcer on the posterior wall of the stomach.

Dr. R. E. **Roberts** (Liverpool) described the radiological appearances in Paget's disease and malignant bone conditions. In the former syndrome the bone appeared blurred and softened and its gross lamellation was altered. When the skull showed a homogeneous alteration it might be necessary to examine the rest of the skeleton, but the diagnosis was usually clear. In the sclerotic type of the disease the appearances might be like those of the sclerosing type of metastases. He described various forms of bony metastases and other new growths.

Dr. **Gilbert Scott** (London) described spondylitis in young persons. The condition was, he said, due to an early infection of the sacro-iliac joint, probably by tuberculosis. The early stages were hardly ever seen, but he had found them in a number of young patients complaining of "wandering" pains. He thought that the infection spread along the spine.

Dr. L. A. **Rowden** (Leeds) ascribed the contralateral pain in some cases of renal calculus to a translucent stone in the kidney on the painful side. He suggested that the opacity of a sinus with a hypertrophic mucous membrane was chiefly caused by the exclusion of air. Carcinoma of the thyroid was, he said, a possible unsuspected cause of bony metastases.

Dr. A. E. **Barclay** (Cambridge) calculated that the cost of all the examinations recommended by the speakers would amount in London to about £65. He suggested that it was the clinician's business to tell the radiologist where to look.

Dr. J. L. **Delicati** (Bristol) mentioned that good results had been obtained at Bath in juvenile spondylitis by keeping patients on their backs until the infective process had died down. The thoracic muscles were exercised regularly and the hips were moved once a day to prevent adhesions.

Dr. J. B. **Burt** (Buxton) said that sciatica was hardly ever found in cases of extensive inflammation of the intervertebral joints, but that it was very common in osteo-arthritic spondylitis.

Dr. **Brailsford** replied that in cases of marked change with ossification of the intervertebral joints the condition was one of ankylosis and therefore not painful. In osteo-arthritis the joints were eroded and their sharp edges cut into the villi which formed round them, causing great pain. He had not intended to suggest that the radiologist should carry out all the expensive examination implied by Dr. Barclay.

REVIEWS AND NOTICES OF BOOKS

Electro-Surgery

By Howard A. Kelly, M.D., LL.D., F.A.C.S., and Grant E. Ward, M.D., F.A.C.S. London: W. B. Saunders Co., Ltd. 1932. Pp. 305. 35s.

The field of usefulness of high-frequency currents has been greatly enlarged in recent years by advances in design of apparatus and research on the factors influencing current effects. In this book information has been collected relating to the whole field of surgery where high-frequency currents may play a part. So much advance has been due to the work of American investigators that it is fitting that this task should have been performed by two well-known transatlantic surgeons. The book supplies for the English-speaking world a text-book corresponding to the admirable German volume by Franz Keysser which appeared last year. It is built up on very similar lines, beginning with the history of the subject and proceeding to a useful account of the physics of high-frequency currents and their method of production. Though the authors appear to use a spark gap apparatus at least for electro-coagulation, yet they have a high opinion of vacuum-tube machines and predict the use of these exclusively in the future.

The next sections of the book describe the physiological effects of currents and laboratory results. Chapters follow on general principles and detailed technique, whilst the remainder of the book gives accounts of regional methods and the results in typical patients. In the urological section perurethral application of radium to bladder tumours finds a place, because Hugh Young, who writes on this subject, makes it a practice of using electro-coagulation and radium in combination both for benign and malignant tumours. The removal of prostatic obstruction by electro-surgery is well described, and also the management of brain tumours. The work meets a need in surgical literature.

The Discharging Ear

By Arthur G. Wells, B.S., M.B., D.P.H., Aurist to the Downs Hospital for Children; Principal Assistant Medical Officer to the London County Council. Pocket Monographs Series. London: John Bale, Sons and Danielsson, Ltd. 1932. Pp. 92. 3s. 6d.

This little book partly overlaps the field covered by Mr. Mollison's on acute otitis media in the same series; but Dr. Wells includes also diseases of the external auditory meatus, and the important subject of chronic suppurative otitis media, or chronic otorrhœa. For the treatment of the latter, Dr. Wells is an enthusiastic advocate of zinc ionisation, which has been widely adopted in the treatment of large numbers of school-children by county councils and similar bodies, for it acts quickly in those cases in which it is effective, and thus lowers the number of attendances. But to be successful the technique must be carefully observed, especially the thorough cleaning of the ear beforehand, and the filling of the whole of the tympanum and meatus with the ionising fluid. Dr. Wells divides chronic otorrhœa into three groups: (1) cases suitable for ionisation when first seen, in which the trouble is confined to the tympanum—these form about one-half of the total cases of chronic otorrhœa; (2) cases unsuitable when first seen, which may be made suitable by treatment of granulations, or of tonsils and adenoids or septic nasal conditions; and (3) cases which cannot be made suitable because of caries, or of disease in the attic or mastoid. A careful and thorough description of the technique of ionisation is the most valuable part of a useful little book.

A Text-book of Biochemistry

Third edition. By A. T. Cameron, M.A., D.Sc.Edin., F.I.C., F.R.S.C., Professor of Biochemistry, Faculty of Medicine, University of Manitoba; Biochemist, Winnipeg General Hospital. London: J. and A. Churchill. Pp. 548. 15s.

This book, which is based on a series of lectures given to students, has reached its third edition in three years. It is intended primarily for medical students who already possess a sound knowledge of organic chemistry, but it will also be found useful by students of science, since the author has included in smaller print some sections not essential for students of medicine but of value to the student of science who needs an introduction to biochemistry. The third edition is somewhat larger than the previous ones, and a new chapter has been added on tissue respiration and muscular activity. Endocrine secretions have now been considered worthy of a chapter to themselves, and those dealing with catalysis, enzymic synthesis, and the vitamins have been extended. The book is now thoroughly up to date, and should prove as successful as its predecessors. The author has had much experience in teaching, and knows well the requirements of the medical student. His subject matter is presented clearly, and in the order in which the student can most easily obtain a good knowledge of the groundwork of biochemistry.

Mammal-like Reptiles of South Africa

And the Origin of Mammals. By Robert Broom, D.Sc., F.R.S. London: H. F. and G. Witherby. 1932. Pp. 376. 25s.

This work, issued under the auspices of the Carnegie Corporation and the Research Board of the Union of South Africa, has long been overdue. The investigation of the fossiliferous beds of the Karroo System began in 1838, and the results have been published at different times, in many scattered papers—more than 100 of them from the pen of Dr. Robert Broom. Now, for the first time, the subject has been dealt with in a form worthy of its importance. The shales and mud-stones known as the Karroo System spread over a large part of South Africa, and appear to have been brought from the North by a huge river, comparable in size to the Nile or the Mississippi. Covering an area of some 200,000 square miles, and of an average thickness of perhaps 2000 feet, they contain, Dr. Broom estimates, the fossil remains of at least 800,000,000,000 animals. Of these, 1200 skulls, belonging to some 350 species of Permian and Triassic reptiles have been collected, and it seems probable that there remain countless species yet to be described. The greater part of the work is taken up with descriptions of these 350 species: dinocephalians, therocephalians, gorgonopsidians, anomodonts, and cynodonts. The development of the mammal-like characteristics can be traced in an ascending scale from Permian to Triassic—the single temporal arch formed by the squamosal and jugal, the teeth differentiated into incisors, canines, premolars, and molars; and the monotreme-like structure of the shoulder-girdle—at least the main line of evolution is indicated. At this descriptive work Dr. Broom is at his best, and comparative anatomists owe him a debt of gratitude for his concise statement of fact, and clear, if not beautiful, illustrations. In his interpretations and inferences however he is at variance with much of current thought, and those "pundits of London" who refused to publish his work in 1896 will raise their eyebrows at his conclusions on evolution. Mutations, Lamarckism, Darwinism are unsatisfactory, "We are almost driven to assume that there is some controlling power which modifies the animal according to its needs and that the changes are inherited . . . Apart from minor modifications evolution is finished. From which we may perhaps conclude that man is the final product; and that amid all the thousands of apparently useless types of animals that have been formed some controlling power has specially guided one line to result in man." This will appear to many biologists a startling doctrine.

Technique chirurgicale

Estomac et duodenum. By PIERRE RHÉAUME, Professeur à l'Université de Montréal. Paris: Masson et Cie. 1932. Pp. 260. Fr.50.

Prof. Rhéaume's object is to make known to the French surgical world the manner in which operations on the stomach and duodenum are performed in Canada. This he achieves by clear descriptions and numerous illustrations in line and in tone. The general methods used resemble those familiar in this country. The first chapter, on the evolution of surgical technique, is interesting. In it we read that Travers of London in 1812 made the fundamental observation that union of hollow viscus to hollow viscus takes place only where at least one applied surface is covered with peritoneum. The advantages of nitrous oxide and oxygen are well emphasised in a chapter devoted to anæsthesia, whilst the preparation and after treatment of patients receive full discussion. Of special interest is the author's advocacy of the use of Murphy's button and of the Depage-Janeway method of gastrostomy. Several methods of gastropexy are described, but the question whether they should ever be employed does not receive consideration. For the sake of completeness the author seems to have described a number of operations that he does not himself practise. This is a useful and interesting book.

Pyorrhœa Alveolaris

The Cartwright Prize Essay of the Royal College of Surgeons of England. By F. W. BRODERICK, M.R.C.S., L.D.S. London: John Bale, Sons and Danielsson, Ltd. Pp. 88. 7*s.* 6*d.*

THE views put forward by Dr. F. W. Broderick on the ætiology of dental caries and pyorrhœa have attracted considerable attention during the last few years. The difficulty of explaining the origin of these diseases on the basis of a purely local causation is so great that there is a general willingness to believe that they depend primarily on some metabolic condition, and the theory that pyorrhœa results from a condition of alkalosis seems, on the face of it, one which should receive serious attention. According to Broderick's thesis, any condition which leads to an anoxæmia brings about a diminution of the CO_2 content of the blood; the serum calcium then becomes in excess of that which the blood can hold, and some of it must be deposited. This leads to the formation of subgingival tartar round the teeth, and this in turn causes a marginal gingivitis which is the forerunner of true pyorrhœa. The infective factor is secondary and represents merely the settlement of bacteria in the damaged tissues. A further factor on which Broderick lays great stress is the stability of the autonomic endocrine system on which depends metabolic balance. The chain of argument with which this thesis is buttressed is somewhat intricate. Dr. Broderick quotes a number of authorities, and shows much ingenuity in assembling a formidable array in support of his views. But he does not show much discrimination, and the experiments, hypotheses, and speculations quoted vary greatly in significance. He has stated his theory in a way which makes it comparatively easy to follow, however, and even if it is not generally accepted he will have performed a useful service in suggesting that dental disease is not a purely local condition.

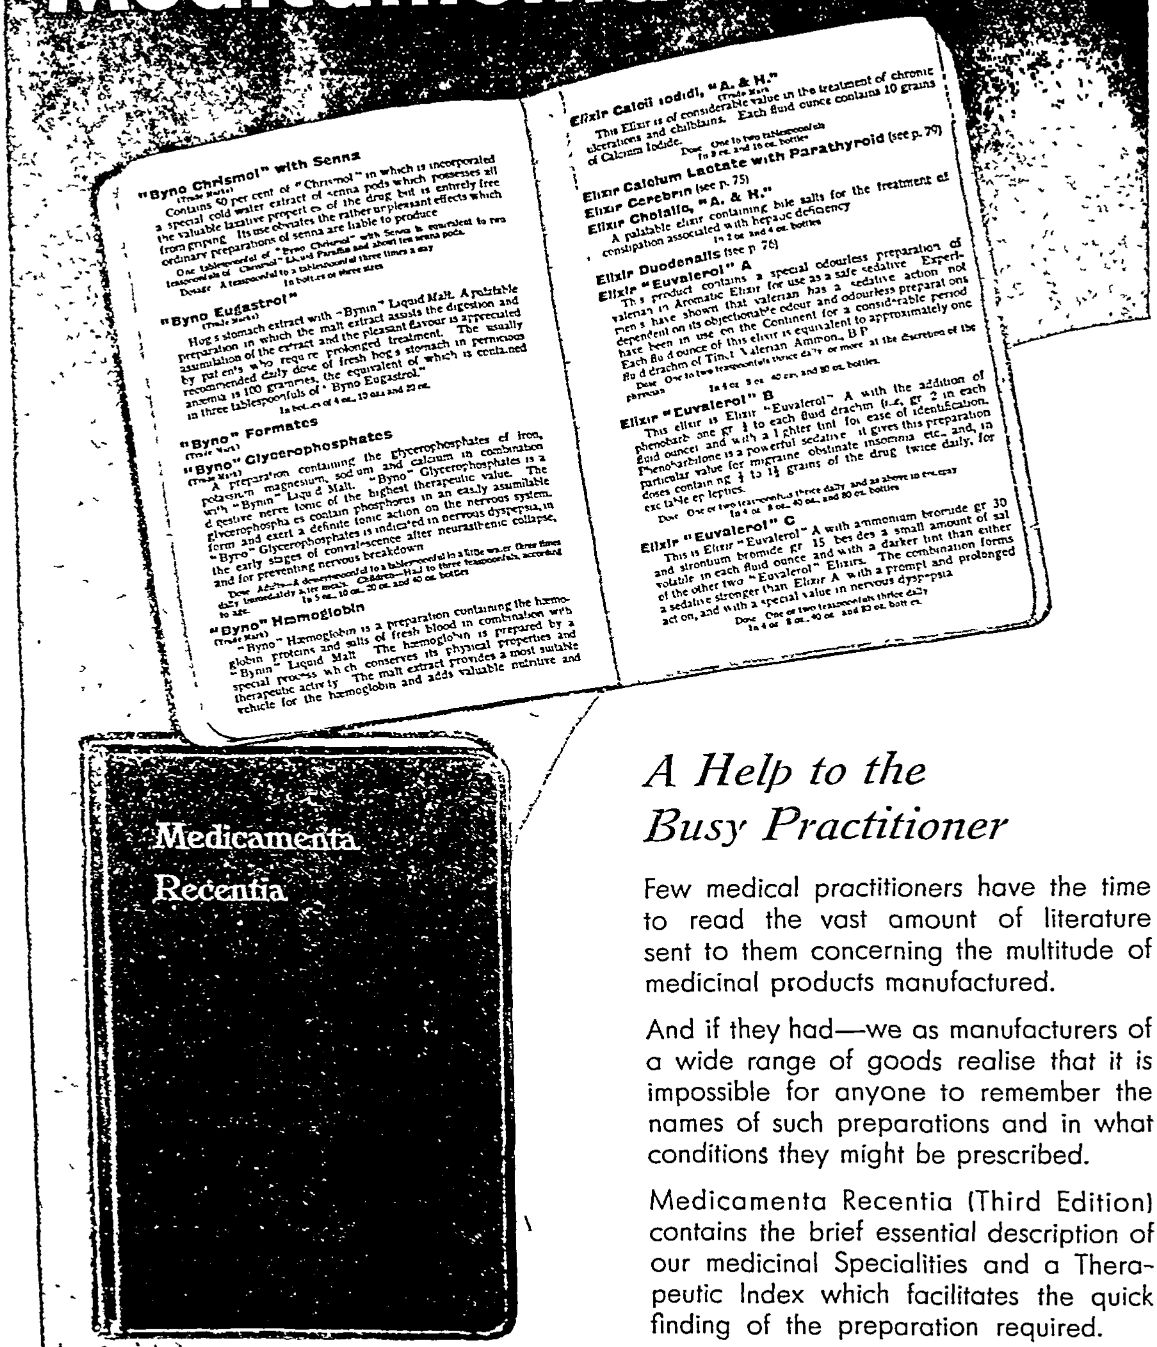
Clinical Endocrinology of the Female

By CHARLES MAZER, M.D., F.A.C.S., Assistant Professor of Gynecology and Obstetrics, University of Pennsylvania; and LEOPOLD GOLDSTEIN, M.D., Demonstrator of Obstetrics, Jefferson Medical College, Assistant Gynecologist to Mount Sinai Hospital. London: W. B. Saunders Co., Ltd. 1932. Pp. 519. 30*s.*

THE advance which has been made in the physiology of reproduction since the work of Allen and Doisy is remarkable. The amount of work done on the ovarian and pituitary hormones in recent years is indicated by the fact that this monograph contains 649 references, most of them to papers published in the last ten years. Unfortunately many of the results obtained seem contradictory; often they have been wrongly interpreted. The time was therefore ripe for the competent review which has here been supplied. The individual hormones are first described under the headings: methods of extraction, physiological effects, and therapeutic action. Œstrin and progestin are fully discussed, and then follows a summary of the work on the anterior pituitary hormones. The authors take the view that the evidence for the existence of two principles (prolan A and B of Zondek, rho I and rho II of Wiesner) is inconclusive. A section on the growth hormone completes a masterly summary of modern work which should be brought to the notice of all who are interested in this branch of endocrinology. This high standard is not, unfortunately, maintained throughout the book; on the clinical side the authors show a tendency to be too optimistic on what appears to be insufficient evidence. It must always be remembered that in the type of case amenable to hormone therapy improvement often follows irrespective of treatment. The authors obtained no results from the administration of anterior pituitary hormones to cases of repeated abortion; indeed, in their experience, therapy along these lines does more harm than good. The records of the method of demonstrating œstrin and other hormones in the blood are interesting; the technique deserves more attention than has generally been paid to it in this country.

The book deserves wide publicity.

Medicamenta Recentia



"Byno Chrismol" with Senna
(Trade Mark)

Contains 50 per cent of "Chrismol" in which is incorporated a special cold water extract of senna pods which possesses all the valuable laxative properties of the drug but is entirely free from griping. Its use obviates the rather unpleasant effects which ordinary preparations of senna are liable to produce.

One tablespoonful of "Byno Chrismol" with Senna is equivalent to two teaspoonfuls of "Chrismol" Liquid Paraffin and about ten senna pods.

Dosage A teaspoonful to a tablespoonful three times a day

In bottles of three sizes

"Byno Eugastrol"
(Trade Mark)

Hog's stomach extract with "Bynin" Liquid Malt. A palatable preparation in which the malt extract assists the digestion and assimilation of the extract and the pleasant flavour is appreciated by patients who require prolonged treatment. The usually recommended daily dose of fresh hog's stomach in pernicious anæmia is 100 grammes, the equivalent of which is contained in three tablespoonfuls of "Byno Eugastrol."

In bottles of 4 oz., 10 ozs. and 20 oz.

"Byno" Formates
(Trade Mark)

"Byno" Glycerophosphates
(Trade Mark)

A preparation containing the glycerophosphates of iron, potassium, magnesium, sodium and calcium in combination with "Bynin" Liquid Malt. "Byno" Glycerophosphates is a digestive nerve tonic of the highest therapeutic value. The glycerophosphates contain phosphorus in an easily assimilable form and exert a definite tonic action on the nervous system. "Byno" Glycerophosphates is indicated in nervous dyspepsia, in the early stages of convalescence after neurasthenic collapse, and for preventing nervous breakdown.

Dose Adults—A dessertspoonful to a tablespoonful in a little water three times daily immediately after meals. Children—Half to three teaspoonfuls, according to age.

In 5 oz., 10 oz., 20 oz. and 40 oz. bottles

"Byno" Hæmoglobin
(Trade Mark)

"Byno" Hæmoglobin is a preparation containing the hæmoglobin proteins and salts of fresh blood in combination with "Bynin" Liquid Malt. The hæmoglobin is prepared by a special process which conserves its physical properties and therapeutic activity. The malt extract provides a most suitable vehicle for the hæmoglobin and adds valuable nutritive and

Elixir Calcii Iodidi, "A. & H."
(Trade Mark)

This Elixir is of considerable value in the treatment of chronic ulcerations and chilblains. Each fluid ounce contains 10 grains of Calcium Iodide.

Dose One to two tablespoonfuls

In 8 oz. and 16 oz. bottles

Elixir Calcium Lactate with Parathyroid (see p. 79)

Elixir Cerebrin (see p. 75)

Elixir Cholalic, "A. & H."

A palatable elixir containing bile salts for the treatment of constipation associated with hepatic deficiency.

In 2 oz. and 4 oz. bottles

Elixir Duodenalis (see p. 76)

Elixir "Euvalerol" A

This product contains a special odourless preparation of valerian in Aromatic Elixir for use as a safe sedative. Experiments have shown that valerian has a sedative action not dependent on its objectionable odour and odourless preparations have been in use on the Continent for a considerable period. Each fluid ounce of this elixir is equivalent to approximately one fluid drachm of Tinct. Valerian Ammon., B.P.

Dose One to two teaspoonfuls thrice daily or more at the discretion of the physician.

In 4 oz., 8 oz., 40 oz. and 80 oz. bottles.

Elixir "Euvalerol" B

This elixir is Elixir "Euvalerol" A with the addition of phenobarbitone gr. ¼ to each fluid drachm (i.e., gr. 2 in each fluid ounce) and with a lighter tint for ease of identification. Phenobarbitone is a powerful sedative; it gives this preparation particular value for migraine, obstinate insomnia, etc., and, in doses containing ¼ to 1½ grains of the drug twice daily, for excitable epileptics.

Dose One or two teaspoonfuls thrice daily and as above in epilepsy.

In 4 oz., 8 oz., 40 oz. and 80 oz. bottles

Elixir "Euvalerol" C

This is Elixir "Euvalerol" A with ammonium bromide gr. 30 and strontium bromide gr. 15 besides a small amount of sal volatile in each fluid ounce and with a darker tint than either of the other two "Euvalerol" Elixirs. The combination forms a sedative stronger than Elixir A with a prompt and prolonged action, and with a special value in nervous dyspepsia.

Dose One or two teaspoonfuls thrice daily

In 4 oz., 8 oz., 40 oz. and 80 oz. bottles.

A Help to the Busy Practitioner

Few medical practitioners have the time to read the vast amount of literature sent to them concerning the multitude of medicinal products manufactured.

And if they had—we as manufacturers of a wide range of goods realise that it is impossible for anyone to remember the names of such preparations and in what conditions they might be prescribed.

Medicamenta Recentia (Third Edition) contains the brief essential description of our medicinal Specialities and a Therapeutic Index which facilitates the quick finding of the preparation required.

A copy will be sent on application.

AN EMPIRE PRODUCTION
OF GREAT VALUE TO THE INVALID

Burgoyne's Tintara

OBTAINABLE OF ALL WINE DEALERS

Ferruginous

THIS PURE AUSTRALIAN WINE introduced in 1871, has been highly recommended by the Medical Profession in all cases where strength and nerve force have required building up. In anæmia, debility, neurasthenia, and in convalescence after any illness, this full-bodied, generous wine, palatable as well as health producing, has proved itself the finest of all natural stimulants.

Sample Bottle sent free in the United Kingdom, on receipt of professional card.

ABSOLUTELY PURE

P. B. BURGOYNE & CO., Ltd.,
Burgoyne House, Dowgate Hill, London.

THE LANCET

LONDON: SATURDAY, SEPTEMBER 24, 1932

THE PSYCHOLOGY OF DELINQUENCY

In his attempt to control natural processes the human agent may work by the light of tradition, by rule of thumb, or, in this scientific age, by applying the results of a careful preliminary study of the processes. Such methods failing we try to find out why. In the control of our criminals and delinquents it would be rash to say that we use even rule of thumb, for the published careers of the men tried for their share in the late mutiny at Dartmoor, with the appalling lists of repeated terms of lengthy imprisonment, exclude any empirical justification of our penal system. This is, however, so traditional that any challenge to it is likely to call up every kind of opposition—anger, derision, or imperturbability. Grafted to tradition there is a theory, based upon a belief in intelligent selfishness as the foundation of behaviour, that a well-adjusted scale of punishment suffices to ensure good conduct, that when a criminal gets what we think he deserves he will cease from crime and that fear of punishment will keep away recruits: a perfect theory with only one defect. That defect, however, prompts some people to apply the scientific method in finding out why criminals are what they are, and how society can best deal with them; to handle crime and delinquency, that is, just as we handle other urgent problems.

This scientific aim implies the study of the material, of the criminal himself; apart from the light that psychopathology throws upon social maladjustments in general, special work has been done in America by Healy and in this country by Hamblin Smith, whose book on the "Psychology of the Criminal," now recognised as a landmark in English criminological literature, we welcomed on its appearance.[1] Dr. Grace W. Pailthorpe, with assistance from the Medical Research Council, has been at work for over five years investigating psychologically the inmates of prisons and preventive and rescue homes, and her results are now available under the title Studies in the Psychology of Delinquency.[2] The cases studied numbered 200, and the completeness of the individual investigations shows a thorough command of modern psychological technique, including that most difficult of all, the removal of the suspicion that the investigator is busied with moral judgments. In the prison (Holloway) the worker was allowed easy access and seems to have received full encouragement, but it is easy to read between the lines and deduce that the authorities of rescue and preventive homes still distrust modern methods. A stipulation that the investigation was to be in mental testing alone was one of the factors that made one establishment unsuitable for the purposes of the work, and Dr. Pailthorpe notes that some of her continental colleagues, whom she visited and whose methods she describes, agreed that superintendents are very unwilling for any treatment that does not act by magic or which entails time for its fulfilment. Yet the main lesson of the report is the need for treatment. The case-histories are often long records of misery arising not merely from material circumstances, but from inner difficulties. There are 111 cases (56 prison, 55 preventive) for whom psychological treatment in one form or another is deemed necessary: in addition, mental defectives and constitutional inferiors require segregation or supervision. Dr. Pailthorpe estimates that of her prison cases 7 per cent. are unlikely to become recidivists, 43 per cent., if psychologically treated, may not become recidivists, 13 per cent. will become recidivists unless treated, perhaps permanently, in hospitals or asylums, and 37 per cent. will inevitably become recidivists unless carefully supervised or segregated.

Mental conflict, so commonly found in the cases here reported, is evidence of the presence of social sentiment, or there could be no conflict. This sentiment could, it is held, be developed by psycho-analytical treatment or intensive social education, and Dr. Pailthorpe makes the novel plea that we are wasting scientific material as well as public money and human lives. In cases where the time for reclamation, if it were ever present, has gone, she shows that public protection calls for the legal recognition of dangerous types not certifiable, and recalls the paranoid reactions of Brown and Kennedy (both of whom had undergone penal servitude and one a flogging before the murder of police-constable Gutteridge). Of this type she says, "Yet we treat him as a mentally stable individual, who will react in a normal way to correction by refraining from committing the same act again. We let him in and out of prison, to prey upon the public until he kills someone, and then we hang him!" It is time that penology was brought down from the clouds of emotion and unreason, to take its place where cause and effect are studied, and where we shall consider what is instead of what tradition tells us ought to be.

◆

RESPIRATORY EFFICIENCY

Surgeons are now able to get from physiologists guidance about the efficiency of the kidney before undertaking operations on the genito-urinary system and, as Dr. R. A. Young has pointed out, it would be desirable to offer them the same kind of help in the selection of patients for operation on the chest. Search has long been made for some criterion of respiratory efficiency other than the number of pillows required by a dyspnœic patient. Some rough guide may be given by observation of the rate of breathing, the shape and size of the chest, or the degree to which the accessory muscles are coming into action, and by investigation of the amount of hæmoglobin in the blood and possibly of the gases dissolved in it. Apart from these it was frankly hoped that the measurement of the vital capacity might aid the surgeon, but this help has largely foundered on the difficulty of determining a normal standard, and the same fallacy has attended the use of various indexes of ventilating power. The variations in health are too wide. Finally some reliance has been placed on the time-honoured method of determining the expiratory force, reintroduced by **MARTIN FLACK** as a standard in the selection of candidates for the Air Force. But, as Dr. **ALAN MONCRIEFF** points out in a scholarly study on another page of this issue, taken alone this test is probably of little value for the special purpose of investigating respiratory efficiency before thoracic surgery is carried out. But investigators in various lands are still hopeful. An attempt to measure the efficiency of pulmonary ventilation by studying the response to carbon dioxide has been made by **R. GOIFFON**, **R. PARENT**, and **J. WALTZ**,[1] using a spirometer of the concertina pattern to trace the respiratory movements on a revolving drum. The voluntary vital capacity and its component parts—complementary, tidal, and reserve air—is first determined and the subject then continues breathing into the apparatus in which the expired carbon dioxide soon accumulates in sufficient concentration to stimulate the respiration. When the limit of endurance is reached the extra ventilation then recorded is called the reflex vital capacity. In normal subjects with a voluntary vital capacity of more than 2 litres these workers distinguish three classes of respiration according as to whether the reflex vital capacity is above, equal to, or less than 2·2 litres; the relationship between these two values they consider of fundamental importance. For example, an athlete had a voluntary vital capacity of 4·9 and a reflex vital capacity of 4·5 litres, the latter being 90 per cent. of the former. Another subject had a voluntary capacity of 4·6 and a reflex capacity of only 2·2 litres; his "coefficient of utilisation" was only 47 per cent.

[2] Medical Research Council, Special Report Series No. 170. H.M. Stationery Office. Pp. 113. 2s.

Whatever the value of this means of testing the ventilating power of the lungs in healthy subjects it would be asking too much of most patients to breathe into a closed space with an increasing carbon dioxide content. A somewhat less unpleasant method is that suggested by **T. R. HARRISON** and his co-workers in their description of the "ventilation index," which **F. C. TURLEY** and he [2] have recently applied to an investigation of smoking and athletics. The assumption here is that dyspnœa is proportional to the quotient ventilation/vital capacity, with a correction for weight, expected and actual. This index is determined at rest and then after a set series of exercises. It was found by comparison with previous figures determined on normal subjects and on patients after various degrees of exercise that "heavy" smoking (20 or more cigarettes a day) for several years does not significantly diminish the respiratory efficiency in the performance of mild and moderate exercise. Judged by this index athletic individuals are not much more efficient than sedentary ones in the performance of mild exertion, but are considerably more efficient in carrying out moderately severe exercise. An investigation on quite a different line is reported by **F. S. COTTON**,[3] who has studied the variation in the centre of gravity of the body during respiration to determine whether there are any sex differences in respiratory movements. This method depends on the fact that in the supine position the movements of the thorax in a vertical direction do not affect the conditions of equilibrium on the special balance employed, while in the sitting position thoracic movements during inspiration produce a caudal displacement of mass, which is indicated by movement of the balance index. If the ratio of measurement expressed as so many gramme-centimetres of mass displacement in the supine posture to that in the sitting posture be calculated, any decrease in the thoracic element must increase the ratio, while a decrease in the abdominal element of respiration will decrease the ratio. After careful corrections for various factors **COTTON** finds that there is a significant difference between the grouped results for men and women, a decreased value being found for the latter. In other words, there is evidence that women show a definitely increased use of the thorax in respiration as compared with men; a further test indicated that clothing exerted no appreciable restraint in diaphragmatic movement in the subjects examined.

In a recent paper **A. PEIPER** and **O. CAMMANN**,[4] dealing with asphyxial attacks in the premature infant, throw some new light on the behaviour of the respiratory centre. They deny that respiratory disturbances in the newly born are due to hæmorrhages in the medulla (as suggested in a recent annotation in these columns [5]), and bring forward experimental evidence to show that similar disturbances can be produced in animals when the main respiratory centre is poisoned by allowing the inspired air to consist of pure carbon dioxide or pure nitrogen. They produced a type of "gasping" respiration exactly similar to that observed in premature infants, and this they believe is due to a "gasping" centre taking control of the respiration after the main centre is put out of action by being temporarily poisoned. This block of the respiratory centre they put forward as an explanation of the respiratory disturbances in premature infants, the excitability of the main respiratory centre being put out of action by various infections, nutritional disturbances, or temperature changes.

THE TONIC PUPIL

THE Argyll Robertson phenomenon, in which both pupils are either totally inactive or very nearly so to light, but react briskly on stimulation to convergence, is a familiar sign of tabes, and is only found in syphilitic patients. There are, however, other pupillary conditions more or less simulating the Argyll Robertson pupil to which Dr. W. J. ADIE draws attention in an enlightening contribution to our knowledge of the tonic pupil reaction.[1] It is important to distinguish these conditions, since they appear to have no connexion with syphilis nor any grave significance. They have been described by various observers during recent years under the names of tonic pupillary reaction, myotonic reaction, tonic convergence reaction of pupils apparently inactive to light, non-luetic Argyll Robertson pupil, or pseudo-Argyll Robertson pupil. Confusion is the more apt to occur since this reaction also may be associated with absence or diminution of one or more of the tendon reflexes. The essential feature of the true tonic pupil, according to Dr. ADIE, is its behaviour during and after convergence.

> "While the patient gazes at a near object the pupil, often after some delay, contracts slowly and with increasing slowness through a range sometimes greatly in excess of the normal, often down to pinhead size; having been larger, it almost always becomes much smaller than its normal fellow. After the effort to converge is relaxed one of several things may happen: the pupil continues to contract (rare), or remains fixed for several or many seconds (the rule), or begins to dilate at once (common); dilatation once begun proceeds at a rate even slower than that of the preceding contraction, and many seconds, or even minutes, elapse before it regains its usual resting size."

The reaction to light appears to be absent on casual testing, but after a long sojourn in a dark room the tonic pupil can usually be made to contract through a normal range. It is almost always larger than its normal fellow. This contrasts with the behaviour of the Argyll Robertson pupil. Where the contraction of the pupil to convergence and its return to its usual state are rapid, other points of difference are that the tonic reaction is unilateral in about 80 per cent. of the cases, whereas in the Argyll Robertson it is unilateral only in about 5 per cent. The tonic pupil is hardly ever small, and dilates to its full size with mydriatics; the Argyll Robertson pupil is small, the diameter being less than 3 mm. in 80 per cent. of cases, and dilates with difficulty to mydriatics. A large proportion of the patients with tonic pupils are healthy young females. There is no evidence of any but an accidental connexion with either syphilitic or any other disease of the nervous system. When the tonic pupil is associated with diminution or absence of one or more reflexes, loss of one ankle-jerk is the most common abnormality. Asymmetry is indeed not unusual; either knee- or ankle-jerk may be absent on one side only. The symptomatology of the condition appears to be extremely variable. Difficulty of accommodation is the only symptom likely to cause inconvenience to the patient, and it does not always occur. In Dr. ADIE's view many cases of so-called "ophthalmoplegia interna" or "iridoplegia," whose origin is obscure, are of the same nature as the disorder known as tonic pupil. In the past there may have been too great a tendency to suspect a syphilitic taint in such conditions. Dr. ADIE believes that the disorder of which they are signs is one in the production of which no known hereditary or acquired morbid factor plays a part. It runs a benign course without the incidence of further symptoms, and is compatible with long life.

◆

HOSPITAL SWEEPSTAKES

THE voluntary hospitals do not wish their needs to be made a pretext for the legalisation of lotteries, but on the other hand they are not opposed to legislation, and would be willing to accept money derived from properly legalised sources. This, in brief, is the message conveyed by Sir ARTHUR STANLEY in his evidence before the Royal Commission on Betting and Lotteries on Sept. 16th. Only a statistician would complain that the importance of this pronouncement is lessened by the fact that he actually submitted his statement of evidence to only a small number of hospitals (72, of which 52 replied, 40 agreeing with his views). Sir ARTHUR is president of the British Hospitals Association, and his long and intimate connexion with the work of the voluntary hospitals gives him a title to be their spokesman. His evidence may, therefore, be considered as authoritative. He holds that lotteries could best be managed and safeguarded from fraud by the appointment of a statutory body on the lines of the British Broadcasting Corporation. A percentage of the proceeds of public lotteries and sweepstakes would be set aside as a general fund, out of which grants would be made to national organisations for charity; grants to voluntary hospitals, for example, would be made through the British Hospitals Association. He believes that if large sums were given out of the proceeds of lotteries to individual hospitals there would be a tendency for charitable contributions, which now amount to £8,000,000 a year, to diminish seriously. A considerable part of that sum is given by people who oppose lotteries on principle, and who would withdraw their support, while many others would feel that their contributions were no longer needed.

Although Sir ARTHUR believes that the funds for maintenance of hospitals will continue to be contributed by the charitable public, the decline in large fortunes makes it inevitable, in his view, that large sums for capital purposes will be increasingly difficult to obtain. It is this need which he contemplates being met out of a lottery fund without danger of alienating subscribers; and the large sums of money which are at present going to Ireland would be kept in this country and spent on deserving objects at home. Sir ARTHUR's evidence shows an interesting modification of the views he expressed in our columns in May of last year. In a letter written at that time he was sceptical of the value of sweepstakes, pointing out that if £1,000,000 were available for charity as the result of a sweepstake, nearly 1000 hospitals and unnumbered charities would be clamouring for a share, thus taking most of the gilt off the gingerbread. At that time he advocated the legalisation of lotteries in which all the prizes were to be in kind and presented by donors, the whole of the cash proceeds going to the hospital concerned. He still considers that any statutory body appointed to deal with sweepstakes should have authority to licence lotteries on such lines.

---

[1] Brit. Jour. Ophth., August, 1932, p. 449.

Lord LUKE, chairman of the British Charities Association, who also gave evidence before the Commission, described the efforts of the association to raise money by prize competitions; they had come to the conclusion that the public did not subscribe primarily because of the charitable aspect of appeals, but because of the attractiveness of the prizes and their confidence in the association. There was a public demand for prize competitions combining an element of chance with an element of skill. The question whether lotteries should or should not be authorised was one that should be considered on its own merits and not confused with the needs of the hospitals. If the Commission should reach the conclusion that lotteries were desirable, they had better, he said, be run by the State as a method of voluntary taxation for the benefit of the national revenue.

ANNOTATIONS

ARSENIC POISONING FROM A WINE RATION

EPIDEMICS of arsenical poisoning in any country serve as a reminder of the dangers inseparable from the use of arsenic in any form. Manufacturers and fruit growers who use arsenic as a chemical or parasiticidal agent must not be allowed to forget that owing to the solubility of nearly all arsenical salts contamination is easy and usually insidious, for the accident is rarely discovered until a number of serious and sometimes fatal cases of poisoning have occurred. Fifteen persons died in an epidemic of 500 cases due to contaminated wine at Hyères and Toulon in 1888, and in 1901 no less than 6000 cases, with a mortality of 70, due to contaminated beer were reported from Liverpool. A recent occurrence of "mass poisoning" by arsenic is the subject of an interesting communication by Caspar Tropp and Gustav Rauch.[1] The epidemic they describe concerned a French ship's crew—a small community under ideal conditions for control and scientific observation. The wine ration of the crew was 1 litre per day per man; it was proved to contain up to 12 mg. of arsenic per litre, and the characteristic symptoms of arsenical poisoning began to make their appearance about a month after the first issue of the ration. The whole crew of 32 men were affected, although only 6 of them were considered ill enough for in-patient treatment at Hamburg. When these came under the observation of Tropp and Rauch they had been drinking the wine for a period of three months, so that most of the symptoms were of chronic cutaneous type. The first case, a sailor aged 30, developed a rash on the chest, axillæ, internatal folds, thighs, and popliteal spaces, about a month after signing on. There was severe irritation and some peeling of the affected areas. Pigmentation followed subsidence of the eruption, and on the palms and soles there developed marked hyperkeratosis, with anæsthesia of the toes and pain on pressure, so that walking was impeded. At a later date gastric pain and vomiting, lacrymation, and difficulty of visual fixation developed, with loss of weight and debility. The eczematous symptoms yielded in three weeks to intravenous injections of calcium, combined with boracic compresses, and a sulphur salicylic ointment as local treatment. A blood count revealed secondary anæmia. In another member of the crew, aged 38, the symptoms were almost identical. Pain, especially of the lower extremities, was so acute that he could not tolerate the pressure of the bedclothes, and lacrymation was also a marked feature. This patient also presented a reduction both in the hæmoglobin percentage and in the red cells (3,250,000). A third patient admitted taking large quantities of wine; in his case the eruption became bullous with a strong tendency to deposition of dark pigment in the affected areas. Gastric and intestinal symptoms were also marked, and the red cells had fallen to 2½ millions. Pain in the extremities and ocular symptoms were a further feature. Three intravenous calcium injections, followed by thiosulphate of soda, from 0·6 to 1 g. (9·1 g. in all) intravenously, and calcium by the mouth controlled the symptoms after one relapse in a little more than a month. The other three cases were rather less violent in their manifestations, and displayed less hyperkeratoses on hands and feet. The intravenous calcium therapy seemed to allay the intense itching and subjective sensations in all six cases, and probably assisted elimination to a considerable extent, since arsenical eruptions and the characteristic hyperkeratoses not infrequently persist and continue to recur for weeks and months after ingestion of the poison, even under treatment with thiosulphate of soda. The possible sources of accidental arsenical poisoning are many. The chief here recorded are wine and beer (from the sulphuric acid used to invert the sugar necessary for fermentation), medicine (from the administration of salvarsan and its derivatives), and fresh fruit which has been treated for the destruction of parasites. Certain cases from the last-named cause occurred in South Africa in the autumn of last year, the victims having eaten peaches sprayed with a solution of arsenic.

THE NATURE OF CONDITIONED REFLEXES

THE great contributions to neurophysiology, made within the last few years by the schools of Sherrington and Pavlov, have been achieved respectively through the study of the decerebrate and of the normal animal. The Oxford workers have analysed the mechanism of the various reflexes to be obtained from decerebrate animals; both excitation and inhibition have been shown to be active processes. In Russia, Pavlov has investigated the reactions of an intact animal to various stimuli and the linkage of such stimuli to certain responses with such success that even in lay circles the phenomenon of conditioned reflexes is now accepted. A critical analysis of the mechanism of conditioned reflexes by a member of the Sherrington school is especially welcome, not only because it enables us to obtain a better understanding of cortical function, but because it provides a fresh stimulus to further work. Mr. D. Denny-Brown[1] contends that the term "reflex" should only be used for such responses as are inborn, fixed, unwilled, and obtainable in decerebrate preparations following stimulation of definite sensory pathways; in other words, for such responses as are dependent upon fixed anatomical pathways and are not analysed by the cortex. To obtain a true conditioned reflex it is necessary to train the animal and to habituate it to certain stimuli; further, the animal requires to receive a continuous running commentary of its actions by proprioceptive pathways and eventually "satisfaction" to the nervous impulse. In this way a conditioned reflex is more complicated, is less dependent upon inborn anatomical pathways than a spinal reflex, and is really the result of habit formation; in short, such reflexes are flexible as against the inflexibility of spinal reflexes. Is, then, inhibition of a conditioned reflex an active process analogous to that of the spinal mechanisms? It is possible that the inhibition of Pavlov may be simply a negative process dependent upon facilitation of other pathways brought about by distraction and shifting of attention. Viewed in this light, conditioned reflexes differ materially from spinal reflexes, and until our knowledge of cortical processes has been widened, it might indeed be advantageous to limit the term "reflex" to those processes which are fixed and dependent upon definite anatomical pathways and entirely independent of analysis by the cortex.

THE RESUSCITATION OF THE STOPPED HEART

SINCE the discovery that it is possible to restore automatic activity of the heart after cardiac standstill, the various methods designed to achieve this end have often been used with zeal wrongly applied. The possibility of restoring life when death seems actually to have taken place depends on the stimulation of such delicate physiological mechanism that skilled as well as prompt handling of the patient is essential. Dr. Albert S. Hyman, who in 1930 published a paper[2] reviewing the methods generally employed in the attempt to restore normal cardiac activity, has now made a further even more valuable contribution[3] to this subject. He has devised an artificial pacemaker which has been used with success in experimental animals, and which, he claims, can in no case jeopardise a patient's condition, since its use in the normally beating heart is relatively harmless. Hitherto electrical stimulation of the stopped heart has sometimes failed because the operator has placed the whole organ in the circuit, instead of attempting to develop the electric differences of potential, and on other occasions such strong currents have been used as to produce a condition similar to electrocution. The success of intracardiac injections led Dr. Hyman to devise a new method of applying rhythmical stimulation. The effect of such injections is now attributed entirely to the prick of the needle, which generates a focal point of irritability, irrespective of the substance used; it occurred to Dr. Hyman that a special needle electrode carrying a suitable stimulating current might be applied as an artificial pacemaker with the advantage of providing an unlimited number of stimuli. It remained to find the ideal type and strength for such a pacemaker. It was necessary to make an apparatus which would (1) imitate the normal sinus impulse in difference of electric potential, speed of release, rate of discharge, and regularity of rhythm; (2) discharge this current in that part of the heart in which a nearly normal cardiac response would follow; (3) maintain a rhythmic discharge over a controllable period of time; (4) be free from the need of accessory and perishable materials; and (5) be instantly available for emergency conditions. An apparatus which appears to meet these requirements has been devised; it is not unwieldly in size, its weight being 16 lb. It is stated that the apparatus has been used clinically "though the number of patients successfully treated by this method is still very small." It is unfortunate that no case-histories are given; the claim that satisfactory results have been obtained makes it highly desirable that full details should be supplied, especially since it is suggested that the apparatus may have a wider clinical application. Dr. A. S. Parsonnet has put forward the suggestion that it might have a therapeutic use in gross cardiac irregularity, as, for example, in very rapid irregular contractures of the ventricle where all other methods have failed, and the peripheral circulation is reduced to dangerously low levels; the pacemaker needle inserted in one or other ventricle might, it is suggested, control the rate. However this may be, the artificial pacemaker certainly seems to merit extensive trial for the restoration of patients who succumb to cardiac arrest.

THE PATHOGENESIS OF INTRACRANIAL BIRTH-HÆMORRHAGE

A COMPREHENSIVE monograph by Dr. Erik Rydberg[1] presents the results of his original work on the normal and morbid histology of the brain of the new-born infant, as well as on the morbid anatomy, treatment, and prognosis of injured infants. It contains also a critical review of current opinion on the mode of origin of birth-hæmorrhage, with an account of a theory propounded by the author. Dr. Rydberg is unable to accept many of the conceptions upon which the theory of P. Schwartz is based—in particular the significance of fat-granule cells in the cerebral tissues and the production of hæmorrhage by suction effect—and a considerable part of the book is devoted to alternative suggestions which he puts forward. The first four chapters are concerned with histological considerations. In a re-examination of the development of glia in the premature and new-born infant by selective metallic methods, Dr. Rydberg finds reasons for adhering to the Central European school rather than to the Spanish. Thus he supports the Held theory of the syncytial nature of the neuroglia, and rejects Hortega's theory of the mesodermal origin of the microglia; he gives grounds for his belief that these cells originate, in common with the rest of the glia, in the medullary epithelium. The question of so-called "encephalitis congenita" of Virchow is reopened. On the basis of his researches Dr. Rydberg supports the view, already put forward by Wohlwill and others, that the occurrence of stainable fatty particles in the brain of the new-born and premature infant is normal, and is intimately connected with myelination. He suggests that the fat is diffused through the tissues in colloidal solution because, in his preparations, it has not appeared to be intracellular. Typical fat-granule cells with intracellular fatty deposits are, however, present in association with acute brain injury in the new-born. These cells may be derived from a number of sources, including microglia, astrocytes, and mesodermal elements.

[1] Cerebral Injury in New-born Children Consequent on Birth-trauma. With an Inquiry into the Normal and Pathological Anatomy of the Neuroglia. Acta pathologica et microbiologica scandinavica, Supplementum X. Copenhagen: Levin and Munksgaard. 1932. Pp. 247.

In reviewing current explanations of the mode of origin of birth hæmorrhage, Dr. Rydberg accepts the theory of Eardley Holland in so far as it applies to cases which exhibit gross alterations of the cranial shape, but he shares the common opinion that there are many cases of intracranial hæmorrhage to which it does not apply. He rejects Schwartz's suction theory on the grounds that the fœtal head is compressible and suffers a reduction in volume, and that no local expansion of the part below the compressing segment is possible. He considers that the conditions which bring about intracranial hæmorrhage are general rather than local, and he regards as particularly significant the rise of arterial pressure which Cushing has shown to accompany an increase of intracranial tension. It is to this "general circulatory strain," and the over-distension of capillaries which it occasions that hæmorrhages are attributed, but no clear explanation is given of the fact that they almost invariably occur in the venous system. Much importance is attached, no doubt rightly, to the sudden variations of pressure which occur during labour.

An analysis of the post-mortem findings on 75 cases in which death occurred at birth or in the first ten days is supplied. Grossly visible hæmorrhages were found in 58 cases; meningeal hæmorrhage was extremely common (56 cases), but usually it was of slight extent, and there was no clear evidence that it had pathological significance. In about half the cases it was associated with intracerebral or ventricular extravasations. In one case only was meningeal hæmorrhage thought to be the cause of death; Dr. Rydberg regards it as a frequent terminal event. The symptomatology of intracranial damage is discussed in relation to a series of 34 cases exhibiting definite cerebral symptoms. The post-mortem results are fully described and illustrated by some excellent photographs. Six of these brains showed no hæmorrhage, but considerable degenerative tissue change was found. Cerebral hæmorrhage was in many cases accompanied by subcutaneous and visceral effusions. Subsequent observations on children who exhibited cerebral symptoms in the first few days of life, but lived for at least one year, are included. Of the 48 cases recorded, no less than 16 showed an extreme degree of mental defect. Spastic palsies developed in some of these, and also in 6 children whose mental development was not greatly impaired.

Dr. Rydberg expresses the opinion that lumbar puncture is of limited diagnostic and of no therapeutic value; when it is indicated for diagnostic purposes, a small quantity of fluid should be removed by means of a syringe and fine needle. He regards blood transfusion as the most effective form of therapy, and advocates the injection of citrated blood into the superior longitudinal sinus. All who are interested in the problems of birth-trauma will find instruction in this monograph, particularly in the descriptions of the author's material. The theories which he propounds raise interesting speculations, but will probably not be found entirely convincing. Schwartz's theories are dismissed somewhat lightly, on arguments based on analogies drawn from simple mechanical experiment. Much consideration is given to the forces driving fluids from the fœtal head, but none to those acting on the fœtal body and driving fluids towards the head. Nevertheless it may well be that the mechanisms to which Dr. Rydberg has given prominence are important components of the complex ætiology of birth-trauma.

NOISE AND HEALTH

THAT noise has increased enormously in the past quarter of a century will hardly be disputed; whether that increase results in damage to health or in loss of working efficiency is a problem still unsolved, and raises acutely controversial questions. Certainly noise tends to be disliked, especially by those who are unaccustomed to it; but though it is commonly asserted that continuous noise diminishes efficiency and often leads to nervous disorders, very little scientific evidence has been collected in support of this opinion. In the past ten years many of the environmental conditions of industry—ventilation, lighting, heating, hours of work—have been the subject of careful investigation in relation to their effects upon health and efficiency. Very little attention, so far, has been paid to noise. Two Studies in the Psychological Effects of Noise, published this week by the Industrial Health Research Board,[1] are therefore particularly welcome. The experimental investigations reported were carried out in a laboratory and in a factory. Mr. K. G. Pollock and Prof. F. C. Bartlett measured the effect of various noises upon university students carrying out, first, tests involving a simple motor skill—e.g., inserting small pegs into holes on a moving trolley—and subsequently performing simple mental work with and without noise. On the whole it was the exception, rather than the rule, to find a marked diminution of the efficiency of performance under noisy conditions of work. On the other hand, some diminution of efficiency was consistently found in each group of experiments, and with equal consistency the introspective reports agreed that noise—especially loud mechanical irregular noise—was definitely distracting, at least at first. Two conclusions the authors regard as established: (*a*) loud noise is in general prejudicial to efficiency, and its harmfulness is roughly proportional to the difficulty of the work involved; (*b*) nevertheless the psychological and physiological effects due directly to noise have been greatly exaggerated. Many of the apparently ill-effects of noise are, they believe, probably due to social causes. When all kinds of popular statements about the baneful effects of noise are prevalent, it becomes easy for any person who is "off colour," or who fails to adapt himself to his social group, to make noise the butt of his grievance. In both the sets of experiments devised by these workers—those requiring simple motor skill and those requiring mental concentration—"adaptation" to noise was found to take place rapidly, and was apparently maintained without obvious effort for short working periods.

In the laboratory the study must necessarily be confined to such short periods, and is therefore limited to the immediate effects of noise. The factory experiment avoids this limitation but must, however, treat noise as only one of a number of simultaneously operating conditions, the effects of each of which it is not always possible to differentiate. The environment chosen in this experiment, carried out by H. C. Weston and S. Adams, was that of a Lancashire cotton weaving shed in which the noise is continuous and very considerable. Since it was impossible to quiet the looms themselves it was necessary to employ some means of reducing the audibility of the loom noise for the weavers taking part in the experiment. This was done by means of ear defenders fitted into the auditory passage. The results were measured in terms of the weavers' output, and an increase of approximately 1 per cent. was found when the loom noise was reduced. Since weaving is largely an automatic process, a small change in output may indicate a much larger change in the operatives' efficiency, and in this experiment it is concluded that the average personal efficiency of the weavers was increased by as much as 12 per cent. There is, however, some doubt whether this increase can be wholly ascribed to the reduction of noise, since the variation of temperature from week to week was such as might tend to favour production during a number of the quiet weeks. As happens so often under industrial conditions, the complete isolation of the particular factor under inquiry was impossible. A more detailed study of the hourly variations of output during the day under conditions of reduced noise reveals the interesting fact that the greater part of the improvement is to be found at the beginning of the work spells. This suggests the very important conclusion that, even after years of work in a noisy environment, the worker does not become completely adapted or acclimatised to noise, but goes through the process of adaptation daily. With the reduction of noise output shows a tendency to be more regular and less variable from hour to hour and day to day. Taken together both these experimental studies indicate that noise may exercise a disturbing effect upon human efficiency, though probably not to the extent that is commonly asserted. Further work on this subject, both in the laboratory and in industry, is essential. The reports, as is pointed out in the preface to them, open up at least as many problems as they can claim to solve.

SECONDARY PELLAGRA

PELLAGRA is so rare in this country that many doctors may never have seen a case. Its clinical features are characteristic, the most typical being, of course, the dark pigmentation of the skin—pellagrous dermatitis—from which the name is derived. With this skin change, present in nearly all advanced cases, though absent in some 20 per cent. of others, are associated stomatitis, diarrhœa, and mental changes; in a number of cases anæmia is also present, and, more rarely, bony changes in the form of an osteoporosis. It is now generally believed that true pellagra is a deficiency disease due to lack of some food factor which is particularly abundant in yeast, meat, milk, and green vegetables, and has been named P-P in America and vitamin B_2 *in this country*.

Recently a number of cases have been described in which signs of pellagra have developed in patients suffering from severe gastro-intestinal disease, or in whom a limited diet has been maintained over a considerable period in the course of treatment. Dr. E. H. Thaysen[1] reviews the literature on this subject, and adds a further two cases from his own experience of what has been called secondary pellagra. He has been able to collect only some 50 published cases, but it is possible that minor degrees of secondary pellagra complicating gastro-intestinal disease or dietetic treatment may occur. In most of the reported cases a diet insufficient in vitamin B_2 had been taken, but in some, though an adequate diet was given, the patient was apparently unable to absorb sufficient to prevent the onset of pellagra. In one of Thaysen's cases, for example, the patient had been taking an almost purely carbohydrate diet for a month and was then fed on a similar diet through a duodenal tube for a further 19 days—after which she developed diarrhœa, stomatitis, and brownish pigmentation of the hands, nose, abdomen, and legs, with hyperkeratosis; mental changes and osteoporosis appeared later. G. B. Eusterman and P. A. O'Leary[2] report a few cases in which similar symptoms appeared in the course of medical treatment of peptic ulcer, and other authors have noticed secondary pellagra in patients with such diseases as carcinoma of the stomach, ulcerative and "simple" colitis, and carcinoma of the bowel. In many of these cases an achylia gastrica has been found, and appears to precede the disease rather than to result from it.

The diagnosis of secondary pellagra can hardly be made in the absence of the typical dermatitis, but Thaysen draws attention to stomatitis as an early symptom of deficiency of vitamin B_2. The mental depression and apathy characteristic of pellagra seems to respond well to a diet sufficient in this food factor, and this suggests that slight degrees of insufficiency may be a factor in the mental changes common in chronic bowel diseases such as colitis. It is certain that in some cases of chronic colitis, for example, the tendency to give a carbohydrate diet may be carried to excess, and that an increase in animal protein may be of real value. In long-standing gastro-intestinal disease an adequate supply of minced or chopped meat, yeast extract, and fresh fruit juice or vegetables should be ensured.

B.B.C. TALKS

THE discreet programme of autumn talks issued by the British Broadcasting Corporation indicates that the public appetite for general medical information is to be gratified without infringing professional custom. A series of 12 talks entitled The Doctor and the Public, on Monday evenings at 7.10 P.M., will be introduced on Oct. 3rd by Sir Thomas Horder, who will ask and we may hope answer the question: What is Health? The doctor's difficulties, lay fallacies about medical matters, the management of middle age, and the surgery of yesterday, to-day, and to-morrow will be discussed by "a physician," "another physician," and "a surgeon," whose identification may well provide an agreeable evening's pastime for their listening colleagues. One can have four chances at spotting each of the physicians, only three at spotting the surgeon. On Tuesdays at 8.30 P.M. the medical directors of certain child-guidance clinics will, as far as they can, in six simple and practical talks, explain how a child's mind works—what it starts with, its place in the family circle, childish fears, instinct and habit, the child at play; and a final discussion will be held between them on how to cope with difficult children. The mechanism of the adult mind is to be the subject of talks at the same time on subsequent Tuesdays by Prof. Cyril Burt and by the president of the British Psycho-Analytical Society. Prof. Burt will speak on Nov. 8th on studying the minds of others, and a week later on studying one's own mind, and will then give place to his collaborator, who will define what is meant by psycho-analysis and the power of the unconscious, and will then explain the meaning and importance of dreams. The series, like its predecessor, will end with a discussion between the two exponents, the subject being Heart or Head? Talks by "a doctor to a mother" are arranged for Friday mornings, beginning on Oct. 7th. It is assumed, probably with good reason, that a mother will be so eager to consult this unknown doctor—whom she cannot even interrupt with questions—that she will cease firing the electric cleaner or iron at 10.45 A.M. precisely to listen for his message. Probably, however, by a minor adjustment this message could be made to coincide with the recognised break in the morning's activities known as "elevenses," when physical and mental nourishment could be taken together. Incidentally, the sound precepts which will be offered by the physician in charge of the children's department at St. Thomas's Hospital and by his obstetrical and medical collaborators, will be more diligently heeded than if they were set out by the family doctor, who can be exasperated into silence by a voluble explanation why these precepts are inapplicable to highly-strung Peter or delicate Pauline. Promised but still undated is a series of Monday evenings (9.20 P.M.) devoted to talks to unnamed listeners: during this series Mr. Gerald Heard will represent the public in putting questions "To a doctor."

OPENING OF THE MEDICAL SCHOOLS

IN connexion with the opening of the session at the London medical schools the following arrangements are announced:—

Charing Cross Hospital.—Prizes will be distributed on Friday, Sept. 30th, at 4 P.M., in the hospital by Mr. W. R. Halliday, LL.D., deputy vice-chancellor of the university, Mr. George Verity presiding. On the following Saturday and Sunday (Oct. 1st and 2nd) there will be a week-end post-graduate course, admission being restricted to old students of the hospital. On Saturday, at 7.30 for 8 P.M., the annual dinner of past and present students will be held at the Royal Adelaide Gallery, Gatti's Restaurant, Dr. William Hunter presiding.

Guy's Hospital.—The winter session will open on Wednesday, Oct. 5th, at 3 P.M. The Bishop of Southwark will distribute prizes and give an address on Cosmics.

King's College Hospital.—Owing to building operations in the new medical school, no formal ceremony will be held this year at the opening of the session. An intensive post-graduate course is being held on Saturday, Oct. 1st, from 2 P.M. till 6 P.M. A series of post-graduate lectures will be given in the medical school on Thursdays, at 9 P.M., from Oct. 13th to Dec. 8th inclusive, and from Jan. 12th to March 23rd. These lectures, and those held on Oct. 1st, are free to all medical practitioners. The annual dinner of past and present students will be held on Oct. 1st, at 7.30 P.M., at the Connaught Rooms, Great Queen-street, Kingsway, Dr. Godfrey de Bec Turtle presiding.

London Hospital.—A post-graduate course for former students of the hospital only will be held from Oct. 12th to 15th inclusive. The annual dinner for former students will be held at the Trocadero Restaurant on Thursday, Oct. 13th, at 7.30 for 8 P.M.

Middlesex Hospital.—The winter session will be opened in the Queen's Hall, Langham-place, on Oct. 4th, at 3 P.M., when Dr. Douglas McAlpine will deliver the introductory address on Mind and Body, and the Hon. J. J. Astor will distribute the prizes. A "Refresher Course" for former students of the hospital only will be held from Sept. 30th to Oct. 4th. On Oct. 4th, at 7.30 P.M., the annual dinner will be held at the Savoy Hotel, Mr. Eric Pearce Gould presiding.

Royal Free Hospital.—Sir Alan Anderson will deliver the inaugural address and Lady Anderson will present the prizes at the London (R.F.H.) School of Medicine for Women on Oct. 4th, at 3.30 P.M., Miss Elizabeth Bolton, dean of the school, presiding.

St. Bartholomew's Hospital.—The old students' dinner will be held in the great hall of the hospital on Monday, Oct. 3rd, at 7 for 7.30 P.M. Prof. George E. Gask will preside.

St. George's Hospital.—The prize distribution will be held on Saturday, Oct. 1st, when Dr. E. Kaye Le Fleming will deliver an address on the General Practitioner: His Relationship to the State, the Public, and His Profession. The annual dinner will take place on the same day at the Hyde Park Hotel, at 7.15 for 7.45 P.M., Sir Crisp English, F.R.C.S., presiding.

St. Mary's Hospital.—A week-end post-graduate course, open to all medical practitioners without fee, will be held from Sept. 30th to Oct. 2nd in the library of the Medical School. The annual dinner of past and present students will be held on Friday, Sept. 30th, at 7.30 P.M., at the Trocadero Restaurant. Sir Joseph Skevington, F.R.C.S., will be in the chair.

St. Thomas's Hospital.—A short post-graduate course for former students only will be held between Oct. 3rd and 7th. The old students' dinner will take place at the Dorchester Hotel, Park-lane, at 7.15 for 7.45 P.M., on Oct. 7th. Major-General Sir Guise Guise-Morris, R.A.M.C., will preside.

University College Hospital.—The winter session will open on Tuesday, Oct. 4th, when Mr. Wilfred Trotter, F.R.S., will give an address in the Library. The annual demonstrations for old students will take place on Thursday and Friday, Oct. 13th and 14th. The annual dinner will be held on Oct. 14th, at 7.30 P.M., at Hotel Victoria, Northumberland-avenue, Sir George Buckston Browne, F.R.C.S., presiding. The dinner for women students of University College Hospital will take place at the same time and day at the Piccadilly Hotel.

Westminster Hospital.—On Monday, Oct. 3rd, at 3 P.M., the winter session will be opened in the board-room of the hospital, when Mr. Spencer Leeson, headmaster of the Merchant Taylors School, will give an inaugural address on a Vision of Knowledge, Sir Henry Hadow presiding. A special post-graduate course for men graduates only is being given at the Westminster Hospital, under the auspices of the Fellowship of Medicine, from Sept. 19th to Oct. 1st. The annual dinner is to be held at Grosvenor House Hotel, Park-lane, on Saturday, Oct. 1st, at 7.30 P.M., Dr. R. Nimmo Watson presiding.

Royal Dental Hospital.—Prizes will be distributed at the hospital on Oct. 3rd, at 8 P.M., by Lord Riddell, who will give an address on How to Educate the Public about their Teeth. The annual clinical At Home will be held on Nov. 26th, and the dinner of past and present students on the same evening at the Dorchester Hotel, Park-lane, Prof. W. H. Gilmour presiding.

Details of the post-graduate courses noted above will be found in our Medical Diary.

TROPICAL HYGIENE.—The British Red Cross Society will hold a course of seven lectures and demonstrations on tropical hygiene, on Mondays, Wednesdays, and Fridays, commencing Monday, Sept. 26th, at 9, Chesham-street, Belgrave-square, London, S.W. 1, at 5.30 P.M. The course will cover such questions as food, clothing, and medical and sanitary precautions necessary for the preservation of health in hot countries.

SPECIAL ARTICLES

RONALD ROSS, 1857–1932

HIS LIFE AND WORK

RONALD ROSS was born in Almora, in the North-West Provinces, at the foot of the Himalayas. in 857, three days after the outbreak of the Indian mutiny, being the eldest of the large family of General ir Campbell Ross by Matilda Charlotte Elderton, he daughter of a lawyer in London, who at one time wned a considerable property in Brixton. The boy was sent back to England at the age of 8 and given n charge to an uncle who lived in the Isle of Wight, nd he received his early education at the Springhill School, Southampton. It is nteresting to learn from his own memoirs[1] that his early inclinations were owards geometry and the mathematics of music, or those early tastes remained with him through his life, so much so that he has himself said that there was a period when he considered his early malarial work as an episode in a medical career for which he had no great inclination.

SIR RONALD ROSS

[Photograph by Elliott & Fry

In 1875 he entered St. Bartholomew's Hospital as a medical student, and qualified as M.R.C.S. in 1879, when one diploma was sufficient for registration. He was undistinguished in the medical school and had no aptitude for clinical studies, so little, indeed, that at one point in his training he had serious thoughts of becoming an Arts student; microscopy, indeed, was the only subject of the medical curriculum which really interested him. But Sir Campbell Ross was a distinguished Indian soldier and the son of such another, and it was firmly indicated to Ross that entrance to the Indian Medical Service would give him a proper opportunity of continuing the family tradition; so in 1881, in the character rather of an obedient son than a zealous doctor, he entered the I.M.S. On arrival in India he was stationed at different times at Mysore, Bangalore. Madras, Quetta, Moulmein in Burma, and the Andaman Islands, and at all these stations he discharged his professional duties without ever, it seems, manifesting any bent towards scientific investigation. His boyish interest in microscopy was not followed up, and he spent his time in experimenting as a poet while he attacked the problems of higher mathematics with assiduity. This he did under the considerable disadvantage of an imperfect education, the creditable result being that he discovered for himself certain methods of algebraic work which were common knowledge among well-trained students. At the same time he became conscious of the relations between music and mathematics and of the close association of both with metrical composition. His artistic ambitions now found full vent. While he sent mathematical contributions in several special directions but with no success, he wrote a great deal of verse, and drafted a romance, entitled "Child of Ocean"; this novel and the poetical compositions have been republished several times and all have received eulogy for their imaginative and dramatic qualities. Ross became so absorbed in his mathematical and artistic studies that an unusually prolonged term of service without leave lost some of its hardship for him. The Indian Medical Service was at the time undermanned in its junior ranks. The Service stood high in the repute of the profession. but was not attracting young officers as it had done, and, further, included not many scientific workers apart from those who held teaching appointments at the universities. But there was no doubt of the importance of the sanitary work to be done or the strenuous way in which that work was being carried on. Ross accordingly, when, after seven years in India, his term of leave arrived. decided to remain in the career upon which he had embarked. and to employ his time in England in working for and obtaining the D.P.H., a diploma which had just been instituted by the English Colleges. He began his bacteriological studies under E. E. Klein, and in these studies he became deeply absorbed. He obtained an extension of leave in order to continue them, and in other respects his days were fully occupied, for in this year he became engaged and shortly afterwards married his wife, Miss Rosa Bloxam, while he also submitted to English publishers the MS. of his romance. He had here the usual experience of the unknown author, but just as his leave was expiring, having displayed considerable pertinacity on the point, he secured its issue on terms which he must have considered inadequate, but which appear to have been justified by the comparative failure of the work; none the less Ross was heartened by a remarkable number of favourable reviews in his belief that what he had written was worth while.

In 1890 he returned to India, definitely grounded in the science of bacteriology, and when he took up an appointment as staff surgeon at Bangalore, although his interest in literary and mathematical studies remained, he now read assiduously modern medical literature, and grasped the indefinite influence which bacteriology would have upon the prevention of tropical diseases. In 1894, the appointment of staff surgeon having come to an end, he returned to England, when various theories formed and half-formed in regard to the origin and prevention of malaria were laid before Prof. Kanthack, then pathologist at St. Bartholomew's Hospital, who introduced him to Patrick Manson. The part played by Manson, Laveran, and Ross in the elucidation of the problems of malaria is well known. Manson, whose previous work had suggested to him that the intervention of an agent like the mosquito, that is capable of piercing the skin of the human body and absorbing human blood, might prove an explanation of the spread of malaria, welcomed the discovery by Laveran of the malaria parasite as a minute organism living in the red blood corpuscles and multiplying in certain time intervals according to the particular kind of parasite concerned. But the method by which the parasite could pass from one human body to another had not been explained. Manson, from his previous experience, reasoned that the parasite, like the filaria, to pass from man to man required an *intermediary of a blood-sucking character.* He observed certain changes which the malarial organism underwent and believed them to be a manifestation of its development, and at this point he met Ronald Ross. The manner in which Ross took up the idea was characteristic of him. He was by this time a sound bacteriologist as well as an accomplished microscopist, while the vast possibilities for human life that underlay the discovery of the intervening agent between human individuals and the spread of malaria appealed with particular force to his vigorous imagination. Ross traced the connexion between the mosquito and the malaria parasite after investigations conducted under all sorts of difficulties. There was nothing to guide him as to the exact species of mosquito that was concerned in malaria, and although much theorising had been published it was necessary to investigate everything de novo. Many false scents were followed up for three years until at last, in 1898, Ross was able to describe successes in conveying malaria from bird to bird by the medium of mosquitoes fed on malaria-infected birds. The life-history of the malaria parasite was promptly worked out and to the scientific world the demonstration was complete and was immediately confirmed by experiments on voluntary human subjects in malarious zones in Italy.

---

[1] Memoirs, with a Full Account of the Great Malaria Problem and its Solution. London: John Murray. 1923.

Ross, in his memoirs to which reference has already been made, tells the story from his own angle with great fullness, and his reiterated complaints of the apathy of the Indian Government in giving no facilities for the researches as they proceeded were fully justified. In 1899 he retired from the Indian Medical Service; he did so with the knowledge that his share in the grand story of prevention was one without which that story could not have been told. Nor did anyone to whom the facts were clear ever wish to gainsay this. The work of Manson, and, indeed, of other predecessors, formed an introduction; to Ross, and to him only, belongs the credit of setting out the whole truth.

On his retirement from the I.M.S. as a surgeon-major, Ross had accepted an appointment as lecturer on tropical medicine and demonstrator of tropical pathology in the school of tropical medicine just founded in connexion with the University of Liverpool. The school was only in its infancy and the appointment was very informal in that the length of tenure was not mentioned, the only guarantee given on behalf of the school being that the salary of £250 per annum would be paid for a minimum period of three years. He threw himself with ardour into his new activities. He was none the less deeply disappointed with the general reception of the fundamental explanation of the problem of malaria, and at no time did he attempt to disguise his feelings. At bottom he was terribly impatient, and could make no allowance for the fact that whole-hearted conversion in all breasts to unfamiliar doctrines could not be expected, and that until such conversion took place he would not obtain immediate support for large schemes directed to the eradication of malaria, whose probable efficiency remained in doubt. Nor could the inaccuracy of claims to priority, especially from Italy, be detected at this stage. Ross was a poor man with a young family and only a major's small pension, and he had anticipated personally a reward in grants or salary which would make the material future certain for him; he thought that the country, as well as his scientific colleagues, recognising the far-reaching implications of the new knowledge, would welcome the putting in hand at once of the vast organisation which he thought was a crying need. He could not realise that in some *places doubt was inevitable and that criticism,* until explanations were forthcoming or tests performed, must be expected; and he was too ready to see in any opposition to his views the jealousy of rivals. There is no need to dwell on this attitude, for Ross took every opportunity himself of emphasising it publicly; it is sufficient to say that, while with time there was a change of heart, in many important respects Ross's resentment was justified. Manson throughout was Ross's strenuous advocate, and too much stress has been laid on the differences which arose for a time between them. Lister, Allbutt and Osler at home, Laveran, Koch, and Metchnikoff abroad, were stalwart supporters, as were such colleagues at Liverpool as Sherrington and Boyce; but no lead came from the Government, either at home or in India, of the sort for which ample grounds had been furnished.

Ross remained in Liverpool until 1902, and was able from there to arrange visits to various places, especially Sierra Leone, where his plans for clearing up the breeding places of the peccant mosquitoes could be tried out and their efficiency proved. He thus convinced many previous critics of his soundness of view. And he now met leaders of thought and action, and was able to discuss with them the problems as they existed, and so came to perceive that those who had been, as he thought, criminally apathetic, had sometimes material reasons, which could not be disregarded, for not carrying out his designs at once or in their entirety. He lectured much, and was the guest of honour on many important public occasions, when Lister, among others, acclaimed the pertinacity and acumen of his labours and their immense promise. Manson and Osler took public opportunities of following suit, and recognition of a public sort began to pour in. He was elected to the F.R.C.S. Eng., made F.R.S., was appointed C.B. soon afterwards, and in 1902 received the Nobel prize for medicine.

In this year he retired from his post at Liverpool and was for a time in consulting practice in London, but was considerably occupied in visits to malarious regions in many parts of the world, where his advice about organised prevention had been sought. By the Colonial Office he was asked to advise on methods of prevention in Mauritius and Cyprus, and at the invitation of the Suez Canal authorities he did similar work at Ismailia. In 1911 he was promoted K.C.B. But private practice did not come with the rapidity which he had expected, and it was ascertained that a scheme for founding an institute which he would be the director would have a rong appeal for him. But before this could aterialise war broke out in Europe and Ross was ppointed consulting physician in tropical diseases r the Indian troops in England. He was next etailed for service at Alexandria in connexion with e outbreak of tropical dysentery in the Dardanelles, d in 1917 was appointed to the War Office as nsultant physician in malaria. He was promoted ll colonel in 1918, and remained at the War Office r a further year as consultant to the Ministry of ensions. At the close of the war he was created C.M.G., and returned to private practice, but is literary and mathematical pursuits occupied much f his time. The Ross Institute, in accordance with scheme set out previously, was opened by the Prince f Wales in 1926. In the following year Ross started n a long Eastern tour, visiting Malaya, Assam, and urma, and attending the inauguration at Calcutta f a monument commemorating his work—an arch earing a medallion portrait (vide THE LANCET, 927, i., 616) and set up in front of the Presidency ospital, a few yards from the small laboratory here his great discovery was made. Ross's illness ated from an attack of paralysis following his return rom that tour. In 1929 the Ross Award Fund ealised, for the succour of the declining years of imself and his wife, something over £15,000, while is manuscripts and correspondence were bought or £2000 by Lady Houston and presented to the nstitute. Lady Ross died almost exactly a year go.

Among the many honours which Ross received nd appointments which he held there may be numerated, in addition to those mentioned, honorary octorates from Dublin, Leeds, Stockholm, and thens; he was a member of a colonial office dvisory committee, and of the advisory board f the Indian Research Fund. His professional riting was not voluminous. He wrote a book n the prevention of malaria, and many papers on his subject appeared in the *British Medical Journal* nd some in *The Lancet*, while his own contributions o *Science Progress*, which he edited for a time, illusrated a curiously Pythagorean approach to science nd the arts, especially music and metrical composiion. His novels and his volumes of verse were issued in several editions and obtained praise in many quarters. His longest work was his Memoirs, an nteresting and candid book, containing a full account of the various stages which culminated in his great discovery, interspersed with many excerpts from his poetry.

Sir Ronald Ross's long and hopeless illness ended on Sept. 16th with his death at his quarters in the Institute at Putney, where he directed the enterprise founded to commemorate his work. In him medicine has lost a great man and the world one whose work has already produced incalculable benefits while still its potentialities remain undeveloped.

RADIUM THERAPISTS VISITING CLUB.—At the invitation of Dr. Ralston Paterson a meeting of radium therapists was held in Manchester last week-end. Though not primarily a clinical meeting, the visitors from other centres in England, Scotland, and Ireland were given an opportunity of seeing something of the technique and methods of the team of workers at the Manchester and District Radium Institute. The week-end included a visit to the Metropolitan Vickers Electrical Engineering Works. Dr. A. Burrows was elected president of the newly inaugurated Radium Therapists Visiting Club, and Dr. Ralston Paterson secretary and treasurer.

MEDICINE AND THE LAW

The Medical Problems of Accident Insurance

THE law of accident insurance is constantly supplying problems for the practitioner. By far the greatest number of accidents which he is called to treat arise "out of and in the course of" the patient's employment. A fair proportion of the remainder, particularly the serious ones, are street accidents, and many of those which occur in the home are covered by newspaper insurance schemes. Almost invariably the doctor's opinion is sought in the first place on the three great questions of duration of incapacity, liability, and compensation. It may be argued that the "liability" and "compensation" are subjects for discussion only with a lawyer, but in practice it is found that they play an important part in influencing the course of treatment and the progress towards recovery. A recent monograph[1] provides an admirable outline of the law in a manner most suited to the combined needs of intelligent laymen and lawyer. Much of the subject matter written is primarily the concern of insurance companies and lawyers, but several chapters should be of the greatest help to the doctor. The question of liability, in so far as it is a purely medical issue, is dealt with fully under the headings The Doctrine of Proximate Cause, and Personal Accident Insurance. A useful reminder is that it is necessary to distinguish between the immediate or proximate cause, the "causa causans," and the remote cause, or "causa sine qua non," which only indirectly causes a loss or injury in that, if it had not come into operation, the direct cause of the loss would not have come into operation either. A patient insured against a specific accident or disease, who subsequently develops another condition, is thus entitled to compensation if there is no break in the sequence of events leading from the original cause of his disability until the last cause. Where for example an accidental fall from a horse has been followed by disease, either caused by the fall itself, or directly attributable to the enfeebled condition of the assured in consequence of the fall, the death, though caused by disease, is proximately caused by the accidental fall. The operation of the doctrine of proximate cause is not effected by the number of causes that may intervene between the peril and the loss; thus a scratch may produce septicæmia, which in turn develops into septic pneumonia, and results in death. Here there is a definite chain of events leading from a scratch to death, and death is proximately caused by a scratch. If, on the other hand, the sequence of causes is interrupted by the intervention of a fresh cause, the cause of the loss within the meaning of the insurance policy is not the peril insured against, but the intervening cause. It is immaterial, if, by reason of the accident, the patient has been rendered more susceptible to the operation of the intervening causes; thus, where a person weakened by a railway accident is run over by a omnibus, which, owing to his weakness, he is unable to avoid, his death is due, not to the railway accident, but to the street accident. Where there is more than one cause of death or disablement, and where the causes are concurrent in their operation, the loss is probably as much due to one cause as to the other. If, therefore, one of the causes has been insured against, the loss within the meaning of the policy is attributed to the insured cause, and the presence of the concurrent cause, and the fact that it, too, may be the cause of loss is disregarded. It is therefore immaterial whether the onset of the uninsured cause preceded or followed the peril in point of time. Where the assured is drowned whilst bathing, his death is caused by accident, and it is immaterial that he fell into the water in a fainting fit, although the water was so shallow that he would not have been drowned unless he had been unconscious.

---

[1] Welford's Accident Insurance. Second edition. By A. W. Baker Welford, of Lincoln's Inn, Barrister-at-law. London: Butterworth and Co. 1932. Pp. 612. 37s. 6d.

The majority of insurance policies against accident describe the insured injury "to be caused by violent, accidental, external, and visible means." Mr. Welford states that as far as the nature of the policy is concerned, these words probably add nothing to the idea defined by the word accident, since they merely give expression to the essential features of an accident. He goes on to take each word separately, and defines it at considerable length, quoting a large number of decisions—e.g., violence means "without any violence at all," and merely expresses that the injury is due to other than entirely natural causes. An injury was held to be violent, in which the man merely stooped down to pick up a marble, but in so doing he dislocated the internal cartilage of his knee-joint. Another patient, whilst taking off his socks, scratched the skin of his leg with his nail, and ultimately died from the consequences of erysipelas. "External" does not apply to the injury, but to the means which produces the injury; thus, a patient lifting a heavy weight injured his spine, and although his injury was entirely internal, the cause which produced this injury was lifting a weight and therefore external.

A great difficulty in medico-legal work seems to be in finding a satisfactory definition for "accident." Mr. Welford, on p. 168, says "the word 'accident' involves the idea of something 'fortuitous' and 'unexpected,' as opposed to something proceeding from natural causes; an injury caused by accident is to be regarded as the antithesis to bodily infirmity caused by disease in the ordinary course of events." The injury may be a natural result of "a fortuitous and unexpected cause"—e.g., where the assured is run over by a train; or the injury is a fortuitous and unexpected result of a natural cause, where the patient stoops to lift up a heavy burden in the ordinary course of business and injures the spine. On the other hand, an injury is not caused by accident if it is the natural result of a natural cause—where a person with a weak heart injures it by running to catch a train. Students of the trend of judicial decisions in workmen's compensation cases will know that in this type of statutory "accident" the House of Lords has expressly declined to regard a "fortuitous and unexpected" element as a criterion.

A special paragraph (p. 272) deals with surgical operations.

> "If a patient is operated upon, and dies as a result of operation, the immediate cause of death is to be disregarded, and the death of the assured is to be attributed to the circumstances which rendered the operation advisable."

If a patient was suffering from a disease for which he were operated upon, his death is due to disease and not accident. If, on the other hand, the operation has been undertaken to alleviate the consequences of accidental injury, his death is death from accident, within the meaning of the policy.

Chapter 18 is devoted to Employers' Liability, and section 4 of this chapter deals with the Workmen's Compensation Act of 1925. The practitioner often has great difficulty in deciding whether a particular injury is due to accident "arising out of, and in the course of his patient's employment." In the multitude of cases quoted here, it seems that the law is strained in favour of the workman, which cannot be better illustrated than by quoting the second paragraph of p. 547:—

> Where there is no accident in the strict sense of the word, but the combined effect of the workman's physical condition and of the exertion involved in the work upon which he is engaged is to produce death or disablement, the death or disablement is to be regarded as caused by accident within the meaning of the statute. In this case, it is immaterial that the work involves no unusual strain or exertion, or that the workman's physical condition is such that, in itself and apart from the exertion involved, it might have produced the same injury, since the death or disablement, happening as and when it does, is, in fact, the unexpected and undesigned consequence of the workman's act, and accordingly the element of accident is introduced. Thus, where a workman suffering from an aneurysm ruptures it whilst tightening a nut with a spanner, it is immaterial that no more than ordinary exertion was used, or that the aneurysm was so advanced that the workman might have died even in his sleep. (Clover, Clayton & Co., v. Hughes, 1910.)

In the Workmen's Compensation Act of 1925 it was also laid down that a workman must submit himself to as many medical examinations as his employer may wish at the hands of the medical man whom his employer may nominate. In practice it is often found that the medical practitioner is unwilling for his patient to be examined by a second doctor without his being present, which usually means an additional fee payable by the employer: in fact neither the doctor nor the workmen have the right to insist that the panel doctor be present. The index of this useful work seems to be confined solely to legal and insurance terms. Its value, from the medical point of view, would be increased very greatly if there were an index of medical diseases, such as aneurysm, which are mentioned in the text or in the cases quoted. The cases themselves are conveniently tabulated at the beginning of the book.

The Checking of Swabs

At a recent inquest upon the death of a woman in Southport Infirmary post-mortem examination showed that she died from pelvic peritonitis. Death occurred after an operation at which it was discovered that a swab used at a previous operation had been left in the body. It was explained to the coroner's jury that the swabs were brought into the operating theatre in bundles of six contained in drums. On the occasion of the operation in question the sister in charge seems not to have counted the number in each bundle, but to have assumed that each drum contained six swabs as usual. The only explanation of the omission to remove the swab from the body was that the swabs in use were duly checked as contained in each drum of six, but that one drum must have contained seven. The jury very naturally suggested that some system should be adopted whereby such an accident could not possibly happen again. If any system could be evolved which was proof against human error, it would of course be taken into use at all surgical operations; meanwhile the need of supreme care in the checking and removal of surgical appliances and dressings is a lesson which no one must be allowed to forget.

Third Degree Allegations

The *Times* of Sept. 8th prints an account from its New York correspondent of the arrest of a deputy sheriff on a charge of murder in connexion with the death of a prisoner in custody. The prisoner, named Virant, had been arrested on suspicion of being concerned in a murder in a "speakeasy." At the coroner's inquest Virant complained that the police had nearly killed him in their endeavours to make him confess the murder of which he knew nothing. He said he had been struck on the head, and he thought two of his ribs had been broken. "They took turns working on me." The deputy sheriff of a district of Illinois, whose arrest for the murder of Virant is now reported, "knocked me down and kicked me, and jumped on my neck." Virant is said to have been found hanged in his cell. A pathologist who examined his body on behalf of the public authorities said that death was not due to strangulation, but had resulted either from beating or from the effect of "knock-out drops," sometimes used by the police to obtain finger-prints from unwilling prisoners, or from a combination of both.

The truth of these allegations will no doubt be carefully examined. In England the public is extremely sensitive to any suggestion of "third degree" methods on the part of the police. It will be recalled that the suggestion of unfair methods was one of the issues inquired into and reported upon by the commission on police powers, set up after the Savidge incident in Hyde Park a few years ago, and presided over by Lord Lee. The admirably written report of the commission is a public document of no little importance. As is well known, our English police force is comparatively modern when contrasted with the antiquity of our criminal institutions. Before the beginning of the nineteenth century the justices of the peace used personally to concern themselves with the investigation of crimes and the apprehension of suspected persons, while the local constables remained much as Shakespeare has depicted them for us. The evolution of a special force of police with statutory powers of arrest and apprehension and a technique of criminal records has thrust the justices back into a mainly judicial position in these matters. If transatlantic methods of extracting evidence by non-judicial methods goes far beyond anything which this country would tolerate, there are many in England who think that the elaborate safeguards of the liberty of the subject deprive our English police of powers which they need for bringing offenders to justice. The cautionary formula to a suspected person, necessary before any use can be made of his statement or of his answers to questions, undoubtedly makes the task of the policeman difficult. The Home Office has officially repudiated any suggestion that these safeguards unfairly handicap the police or are responsible for the non-discovery of criminals who might otherwise be detected and punished; the police force, however, possibly takes a different view.

The Coroner's Office in Bombay

The Illinois case, noted in the preceding paragraphs, illustrates the remarkable value of the coroner's office as a part of the machinery of criminal investigation in all countries which have taken over these historic items of the English system. The latest issue of the *Journal of Comparative Legislation* (just published), in giving the usual annual summary of statutes recently passed in various countries, happens to deal with the office of coroner in the Presidency of Bombay. The law relating to coroners has remained in force unamended in Bombay for nearly 60 years, and was based almost entirely upon the old principles of the law in England. A recent amendment (Act No. 13 of 1930) makes several changes. A coroner in Bombay need now no longer empanel a jury for every inquest. He need not hold a separate inquest on each of several persons who have met their death in one common accident. If satisfied by preliminary inquiry as to the cause of death, he can permit the body to be disposed of. A suspected person is no longer to be treated as an accused person in the coroner's court where, of course, the investigation is general, and where no formal charge has been preferred against a named individual. A coroner is also now to be equipped with powers for dealing with cases of contempt of court. Finally, proceedings before a coroner can now be stayed where criminal proceedings before a magistrate are under way. Thus Bombay has adopted some of the improvements introduced in England by the Act of 1926.

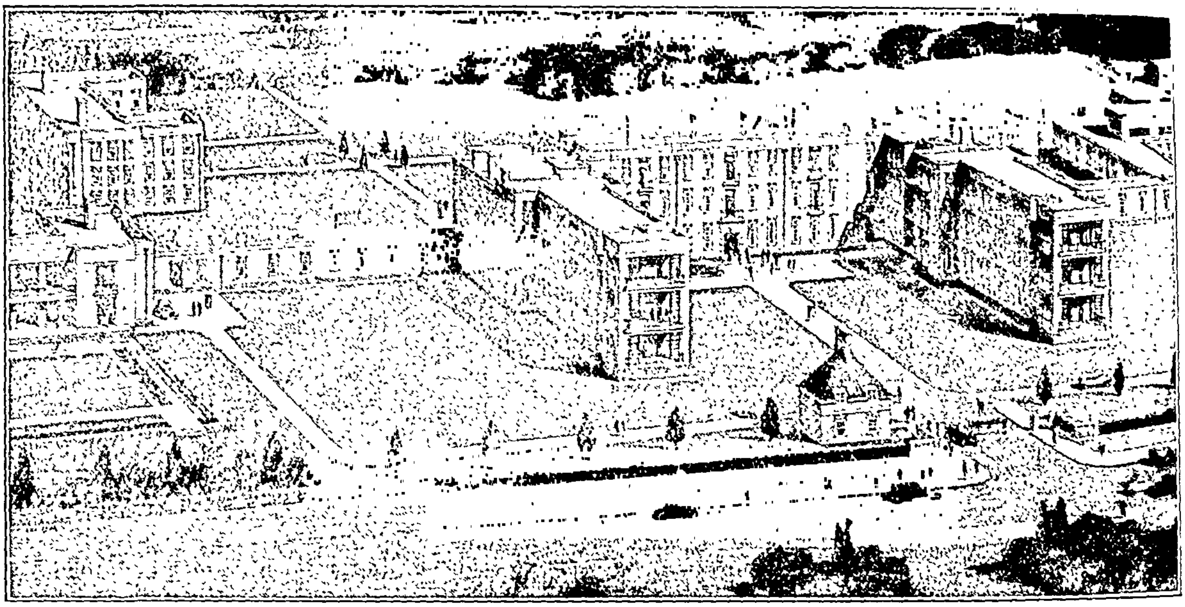
SOUTHEND GENERAL HOSPITAL

THE new general hospital at Southend-on-Sea, which was formally opened on July 26th, will, it is expected, be ready to receive patients towards the end of next month. The hospital serves an area, including Southend, Westcliff, and Leigh, stretching for seven miles along the Essex coast, which has quickly developed into a residential area and holiday resort for Londoners who have elected to live by the sea where it comes nearest to the metropolis. Shortage of accommodation at the local voluntary hospital in Warrior-square, built as a memorial to Queen Victoria's Jubilee and increased by stages up to 96 beds and cots, led to an influx of patients at the Rochford poor-law hospital where the accommodation has been taxed to the utmost. Eight years ago the community was faced with the alternative of admitting that the principle of maintaining a general hospital by voluntary subscriptions had failed, and falling back on the provision of a municipal hospital under the Public Health Acts, or of making a colossal effort to provide a voluntary hospital with 200 or more beds. At this stage, as is common knowledge, Lord Iveagh came to the rescue with the gift of a site of twelve acres in the Prittlewell district, and contributions to the funds amounting from first to last to a total of nearly £100,000. Others were stimulated to benefaction: Mr. E. Cecil Jones gave £10,000 towards a children's wing, Alderman A. Martin offered a life interest on £58,000 for maintenance, with the capital sum on his death. Sums of money came in sufficient to name all the cots in the children's wing.

The site of the hospital slopes gently towards the south, the main entrance being on the southern boundary. As will be seen from the aerial view, the administration block lies centrally with the main corridor running east and west, giving access to the ward blocks, three storeys in height, with flat roofs and large open-air balconies at the southern end. On the left is seen part of the children's block, two storeys in height, which lies east and west. The main ward blocks are at present two in number, space being left for two further blocks which will increase the number of beds by 180 up to nearly 400. The beds are allotted as follows: 60 each for general surgical and general medical cases, 24 maternity cases, 21 paying beds, 8 for eye cases, 2 for casualties, and 44 for children. A feature of the wards is the arrangement of the beds. The arrangement, familiar enough in America, was novel when introduced by the same architects, Messrs. Adams, Holden, and Pearson, in the design for the Birmingham hospitals centre;[1] and has since been adopted by the New Sussex Hospital for Women and Children, of which we reproduce an illustration from THE LANCET of 1931,

---

[1] See THE LANCET, 1930, i., 318.



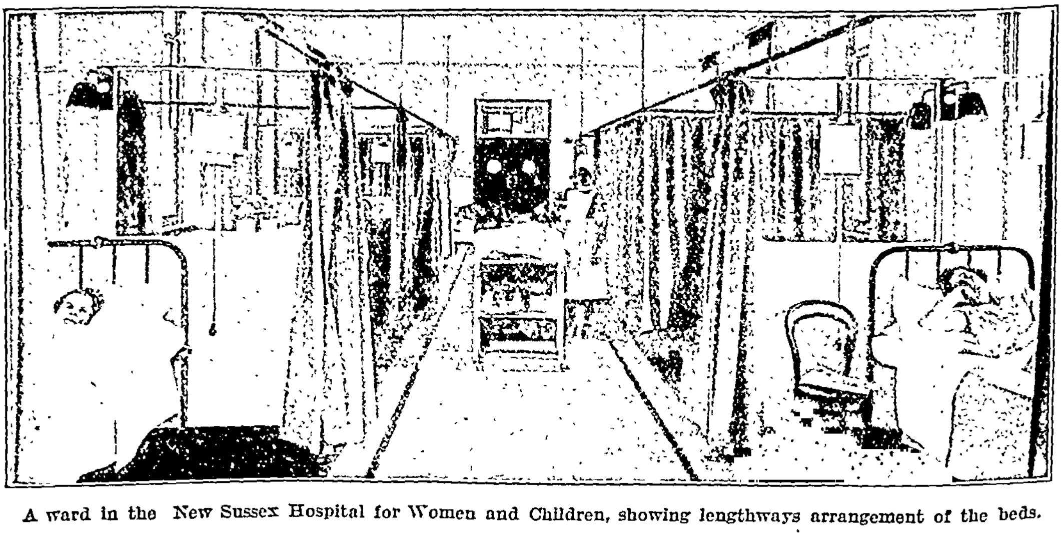
Aerial view of the new General Hospital at Southend-on-Sea.

i., 1382, to show its attractive features. In the usual hospital ward the beds are placed at right-angles to the walls so that the patient is facing the light from the opposite windows and has the radiator near the head instead of the foot of the bed. On the new principle the beds are placed in pairs, parallel to the wall with a window to each bed, separated by a series of partitions of metal and glass connected by rods which enable curtains to be drawn on the corridor side, thus obviating the need of portable screens. Channels in the screen carry the wires for light and listening in, and everything is given a flush finish to facilitate cleaning.

In the children's block all the wards have large folding-doors opening on the balconies so that in fine weather they can be thrown completely open to the south. In this block there are large glass windows between the various wards for complete supervision. The buildings are faced throughout with hand-made local bricks which have considerable variety in colour and texture, thus adding to the interest of the necessarily simple elevations. String-courses and key-stones are in artificial stone, real Portland stone being used in exposed positions such as window-sills and copings. The design was considered of sufficient interest and merit to occupy the whole of a supplement to the *Architects' Journal* for July 20th.

The intention had been to leave the out-patient department at the Victoria Hospital, but this would have complicated administrative problems, and there is now a complete department at the new hospital with six consulting rooms, ophthalmic room, minor operating theatre, dispensary, and medicine room. It is hoped to organise appointments so as to avoid overcrowding and long waiting, and by coöperation between practitioners and hospital staff to ensure to all the personal-timed consultations which are generally available for private patients.

The top floor on the men's side contains 21 beds for paying patients, in wards of 4, 2, and 1 bed each. The intention is to build later an east wing similar to the children's wing on the west to accommodate at least 80 private patients. No contributory scheme for the general hospital has been yet definitely



A ward in the New Sussex Hospital for Women and Children, showing lengthways arrangement of the beds.

arranged, but it is proposed that a person within certain income limits, by paying a regular sum weekly or monthly, can receive treatment without charge. It is claimed with some justice that there is no more complete provincial voluntary hospital in the country, and at the official opening Dr. L. Gordon Hopkins, chairman of the medical advisory committee, referred to three features of the hospital which were to some extent innovations. The first of these was the introduction of a complete specialist medical staff; secondly, the provision of pay beds to meet the needs of members of the community who could not afford nursing home fees and yet found charity distasteful; and thirdly, the setting up of a maternity service where the dangers of the pre- and post-natal periods could be successfully combated.

The staff of the hospital so far as at present appointed is as follows:—Hon. Physicians: Dr. William Evans, Dr. T. Rowland Hill, Dr. R. S. Johnson, and Dr. A. D. Porter. Hon. Surgeons: Mr. Rodney Maingot, Mr. R. H. Campbell, and Sir William Wheeler. Hon. Dermatologist: Dr. A. Burrows. Hon. Radiologist (Diagnostic): Dr. H. Cecil Bull. Hon. X Ray Therapist: Dr. M. H. Jupe. Hon. Ophthalmologist: Dr. D. D. Evans. Hon. Ear, Nose, and Throat Surgeon: Mr. C. Hamblen Thomas. Hon. Orthopædic Surgeon: Mr. B. Whitchurch Howell. Hon. Anæsthetists: Dr. A. P. Cogswell and Dr. W. E. Robinson. Hon. Gynæcologists: Mr. H. Burt-White, Mr. J. Lyle Cameron, and Mr. F. Neon Reynolds. Pathologist: Dr. C. F. Freezer. Pharmacist: Mr. A. C. Adamson. An hon. physician to the electrotherapeutic department is still to be appointed.

PARIS

(FROM OUR OWN CORRESPONDENT)

THE PUBLIC HEALTH POLITICAL PARTY

THE activities of the *Parti social de la santé publique* have not received the attention they deserve from the sanitary reformer abroad. One original feature of the new political party is that at the general election this year its representatives did not stand. What will happen at the next general election is another matter; and it is commonly understood that deputies who fail to keep promises made in 1932 with regard to public health reforms will find a powerfully organised opposition. The driving force behind this party is Justin Godart who is now at the head of the Ministry of Health. The Secretary-General of this new party, which was formed towards the end of 1929, is Dr. Georges Schreiber whose advocacy of the periodic medical examination and the prenuptial medical examination has for several years been conducted with remarkable energy. One of the principles of the party is to appeal to all, irrespective of their politics and religion, to join in the personal and public health movement. Young as it is, the new party has already several important achievements to its credit. As a sequel to a speech made by the president of the association of telephone subscribers energetic measures were undertaken to rendering French post offices cleaner and healthier, and another reform promoted concerns cleanliness of the streets, the pavements in particular. Protests against the fouling of pavements by defæcating dogs have led to the appointment of special services for dealing with this nuisance, and to the doubling of the tax on luxury dogs. Other evils being attacked are the lack of hygienic conditions in trains and railway stations, and the overloading of the school-child's curriculum. The new party hold that a prenuptial medical examination should be compulsory, the prospective parties being not only free to choose their doctor but to follow or disregard his advice as they please. Further activities include a campaign directed towards the present methods of staffing the Ministry of Health. A plan to encourage individual efforts so that the enterprising butcher who keeps his meat under glass, or the milkman who takes special precautions to provide his customers with clean milk gains valuable publicity. On the other hand there is a black list. The offenders whose names are inscribed thereon are given helpful warnings. Even the thoughtless housewife, who shakes her carpets out of the window at all hours of the day, to the discomfiture of the passing school-child, may have to mend her ways in response to propaganda and may find her activities in this respect to be legal only before 7 A.M.

THE CAUSES OF MOTOR ACCIDENTS

A special commission, over which the Minister of Public Health will preside, has recently been appointed to investigate the causes of motor accidents. One of the members of this commission is Dr. Toulouse, who is in charge of the psychiatric and mental prophylaxis clinic of the Henri-Rousselle Hospital in Paris. He has pointed out in a recent interview the curious fact that the public remains unmoved by the thousands of fatal tragedies caused by motoring, whereas it is terror-stricken by even one case of rabies. While many people would still hesitate to enter an aeroplane, no one reflects as he enters a strange motor-car that he is putting his life in the hands of some one of whose capacity to take quick decisions he knows nothing. In 1931 motor accidents caused over 4000 deaths in France, and injured more than 80,000 persons. The remedy Dr. Toulouse is inclined to advocate is a very thorough medical examination of all candidates for driving licences. At present such an examination is required only of drivers of heavy vehicles. At first it would probably succeed in combing out only the most obviously unfit, but it should be possible to tighten up such examinations till they became a very fine comb. Dr. Toulouse is, of course, particularly interested in the mental side of the proposed medical examination, and he is convinced that the psychological element plays a decisive rôle with the driver whose morbid pride leads him to set too hot a pace. Dr. Toulouse has been consulted by taxi-drivers suffering from heart disease and epilepsy and, being tied by the code of professional secrecy, he has been powerless to intervene except by cautioning his patients. The composition of the new commission is not exclusively medical; motor-car manufacturers will be represented on it, and it is hoped that they may be able to throw light on the mechanical causes of accidents such as the combination of too powerful engines with comparatively light cars.

THE DISCOVERER OF IODOFORM

The recent commemoration of the centenary of the death of Georges-Simon Sérullas was the occasion for interesting biographical studies of this remarkable chemist. He was born at Poncin on Nov. 2nd, 1774. In 1791, having just left school, he enrolled himself in a battalion of volunteers, becoming at the same time a student of pharmacy. At the battle of Waterloo, he was the chief pharmacist to the *Grande Armée*. In 1816 he taught chemistry at a hospital in Metz, and between 1824 and 1825 he was president of the Society of Sciences and Art in that town. He was subsequently appointed professor of chemistry

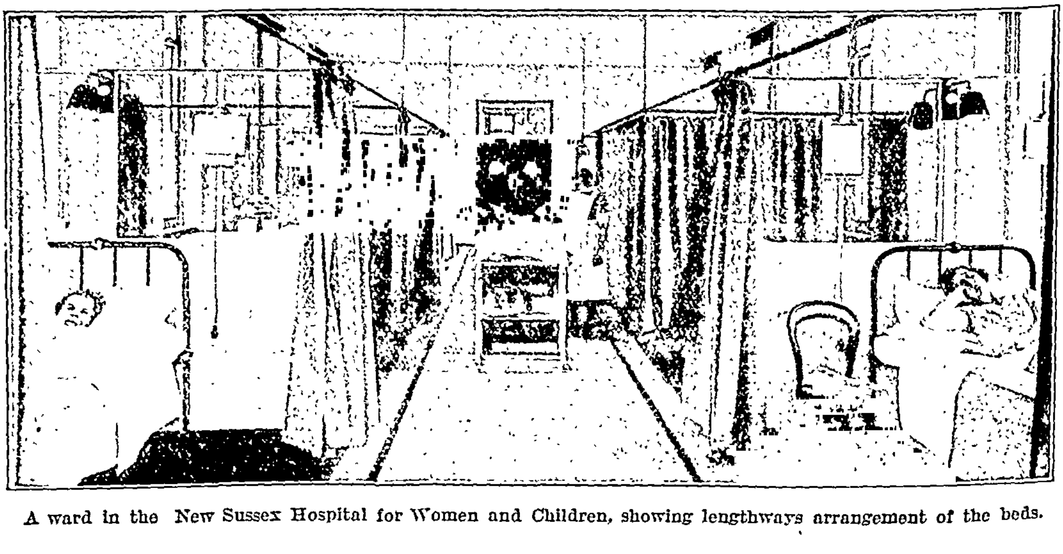
i., 1382, to show its attractive features. In the usual hospital ward the beds are placed at right-angles to the walls so that the patient is facing the light from the opposite windows and has the radiator near the head instead of the foot of the bed. On the new principle the beds are placed in pairs, parallel to the wall with a window to each bed, separated by a series of partitions of metal and glass connected by rods which enable curtains to be drawn on the corridor side, thus obviating the need of portable screens. Channels in the screen carry the wires for light and listening in, and everything is given a flush finish to facilitate cleaning.

In the children's block all the wards have large folding-doors opening on the balconies so that in fine weather they can be thrown completely open to the south. In this block there are large glass windows between the various wards for complete supervision. The buildings are faced throughout with hand-made local bricks which have considerable variety in colour and texture, thus adding to the interest of the necessarily simple elevations. String-courses and key-stones are in artificial stone, real Portland stone being used in exposed positions such as window-sills and copings. The design was considered of sufficient interest and merit to occupy the whole of a supplement to the *Architects' Journal* for July 20th.

The intention had been to leave the out-patient department at the Victoria Hospital, but this would have complicated administrative problems, and there is now a complete department at the new hospital with six consulting rooms, ophthalmic room, minor operating theatre, dispensary, and medicine room. It is hoped to organise appointments so as to avoid overcrowding and long waiting, and by coöperation between practitioners and hospital staff to ensure to all the personal-timed consultations which are generally available for private patients.

The top floor on the men's side contains 21 beds for paying patients, in wards of 4, 2, and 1 bed each. The intention is to build later an east wing similar to the children's wing on the west to accommodate at least 80 private patients. No contributory scheme for the general hospital has been yet definitely



A ward in the New Sussex Hospital for Women and Children, showing lengthways arrangement of the beds.

arranged, but it is proposed that a person within certain income limits, by paying a regular sum weekly or monthly, can receive treatment without charge. It is claimed with some justice that there is no more complete provincial voluntary hospital in the country, and at the official opening Dr. L. Gordon Hopkins, chairman of the medical advisory committee, referred to three features of the hospital which were to some extent innovations. The first of these was the introduction of a complete specialist medical staff; secondly, the provision of pay beds to meet the needs of members of the community who could not afford nursing home fees and yet found charity distasteful; and thirdly, the setting up of a maternity service where the dangers of the pre- and post-natal periods could be successfully combated.

The staff of the hospital so far as at present appointed is as follows:—Hon. Physicians: Dr. William Evans, Dr. T. Rowland Hill, Dr. R. S. Johnson, and Dr. A. D. Porter. Hon. Surgeons: Mr. Rodney Maingot, Mr. R. H. Campbell, and Sir William Wheeler. Hon. Dermatologist: Dr. A. Burrows. Hon. Radiologist (Diagnostic): Dr. H. Cecil Bull. Hon. X Ray Therapist: Dr. M. H. Jupe. Hon. Ophthalmologist: Dr. D. D. Evans. Hon. Ear, Nose, and Throat Surgeon: Mr. C. Hamblen Thomas. Hon. Orthopædic Surgeon: Mr. B. Whitchurch Howell. Hon. Anæsthetists: Dr. A. P. Cogswell and Dr. W. E. Robinson. Hon. Gynæcologists: Mr. H. Burt-White, Mr. J. Lyle Cameron, and Mr. F. Neon Reynolds. Pathologist: Dr. C. F. Freezer. Pharmacist: Mr. A. C. Adamson. An hon. physician to the electrotherapeutic department is still to be appointed.

THE PUBLIC HEALTH POLITICAL PARTY

THE activities of the *Parti social de la santé publique* have not received the attention they deserve from the sanitary reformer abroad. One original feature of the new political party is that at the general election this year its representatives did not stand. What will happen at the next general election is another matter; and it is commonly understood that deputies who fail to keep promises made in 1932 with regard to public health reforms will find a powerfully organised opposition. The driving force behind this party is Justin Godart who is now at the head of the Ministry of Health. The Secretary-General of this new party, which was formed towards the end of 1929, is Dr. Georges Schreiber whose advocacy of the periodic medical examination and the prenuptial medical examination has for several years been conducted with remarkable energy. One of the principles of the party is to appeal to all, irrespective of their politics and religion, to join in the personal and public health movement. Young as it is, the new party has already several important achievements to its credit. As a sequel to a speech made by the president of the association of telephone subscribers energetic measures were undertaken to rendering French post offices cleaner and healthier, and another reform promoted concerns cleanliness of the streets, the pavements in particular. Protests against the fouling of pavements by defæcating dogs have led to the appointment of special services for dealing with this nuisance, and to the doubling of the tax on luxury dogs. Other evils being attacked are the lack of hygienic conditions in trains and railway stations, and the overloading of the school-child's curriculum. The new party hold that a prenuptial medical examination should be compulsory, the prospective parties being not only free to choose their doctor but to follow or disregard his advice as they please. Further activities include a campaign directed towards the present methods of staffing the Ministry of Health. A plan to encourage individual efforts so that the enterprising butcher who keeps his meat under glass, or the milkman who takes special precautions to provide his customers with clean milk gains valuable publicity. On the other hand there is a black list. The offenders whose names are inscribed thereon are given helpful warnings. Even the thoughtless housewife, who shakes her carpets out of the window at all hours of the day, to the discomfiture of the passing school-child, may have to mend her ways in response to propaganda and may find her activities in this respect to be legal only before 7 A.M.

THE CAUSES OF MOTOR ACCIDENTS

A special commission, over which the Minister of Public Health will preside, has recently been appointed to investigate the causes of motor accidents. One of the members of this commission is Dr. Toulouse, who is in charge of the psychiatric and mental prophylaxis clinic of the Henri-Rousselle Hospital in Paris. He has pointed out in a recent interview the curious fact that the public remains unmoved by the thousands of fatal tragedies caused by motoring, whereas it is terror-stricken by even one case of rabies. While many people would still hesitate to enter an aeroplane, no one reflects as he enters a strange motor-car that he is putting his life in the hands of some one of whose capacity to take quick decisions he knows nothing. In 1931 motor accidents caused over 4000 deaths in France, and injured more than 80,000 persons. The remedy Dr. Toulouse is inclined to advocate is a very thorough medical examination of all candidates for driving licences. At present such an examination is required only of drivers of heavy vehicles. At first it would probably succeed in combing out only the most obviously unfit, but it should be possible to tighten up such examinations till they became a very fine comb. Dr. Toulouse is, of course, particularly interested in the mental side of the proposed medical examination, and he is convinced that the psychological element plays a decisive rôle with the driver whose morbid pride leads him to set too hot a pace. Dr. Toulouse has been consulted by taxi-drivers suffering from heart disease and epilepsy and, being tied by the code of professional secrecy, he has been powerless to intervene except by cautioning his patients. The composition of the new commission is not exclusively medical; motor-car manufacturers will be represented on it, and it is hoped that they may be able to throw light on the mechanical causes of accidents such as the combination of too powerful engines with comparatively light cars.

THE DISCOVERER OF IODOFORM

The recent commemoration of the centenary of the death of Georges-Simon Sérullas was the occasion for interesting biographical studies of this remarkable chemist. He was born at Poncin on Nov. 2nd, 1774. In 1791, having just left school, he enrolled himself in a battalion of volunteers, becoming at the same time a student of pharmacy. At the battle of Waterloo, he was the chief pharmacist to the *Grande Armée*. In 1816 he taught chemistry at a hospital in Metz, and between 1824 and 1825 he was president of the Society of Sciences and Art in that town. He was subsequently appointed professor of chemistry at the Val-de-Grâce. It was, however, as early as 1822 that he made the discovery of iodoform. During the British blockade of the continent a competition was organised for discovering the best method for preserving the sugary matter of native vegetables; Sérullas devised a method for preparing syrup of grapes. As late as 1828 he discovered the chemical which, during the Great War, was employed as a poison gas under the name of "mauguinite." Dying of cholera on May 25th, 1832, he was so poor that his friends intervened on his behalf in order that he might be buried at the cost of the State in the Parisian cemetery of Père Lachaise, where he now rests beside Chopin.

BERLIN

(FROM OUR OWN CORRESPONDENT)

FOREIGN ASSISTANTS IN GERMAN HOSPITALS

THE Association of Hospital Assistants has lately complained of the employment in numerous hospitals of medical men with foreign diplomas, although there is no lack of recently qualified Germans who would be glad to work as assistants, for no one is admitted to club practice without having served for three years in a hospital. The Minister of Public Welfare has stated that in Prussia, apart from the university clinics for which the Ministry of Education is responsible, there are 103 hospitals in which altogether 145 foreign medical men are employed. Of these hospitals, 35 belong to religious corporations, 17 are private, and the remainder are municipal or public. The Minister has been informed that certain foreign medical men have acted as if they were duly qualified in Germany: they have prescribed "dangerous" remedies, they have given certificates of death and opinions for law courts, they have attended patients with venereal diseases, thus rendering themselves liable to penalties. The Minister has instructed local authorities that they are not authorised to employ or let employ foreign medical men, that those at present employed are to be discharged and Germans appointed in their stead. The Minister added that there is no reason to prevent foreign medical men from working, as heretofore, voluntarily for the purpose of study under hospital surgeons and physicians.

HOSPITAL STATISTICS

According to statistical records taken by Dr. Dornedden of the German Statistical Office and published in the Reichsgesundheitsblatt, the number of lying-in hospitals and clinics is three times greater than before the war. The obvious reason is that women increasingly prefer to be delivered in an institution where the expenses are not much higher and the trouble is smaller than at home confinements. The number of other hospitals has increased, and the number of beds in still higher proportion, so that, generally speaking, the hospitals have increased in size. While in 1913 4·3 beds existed for each 1000 of the population, that number was 6·2 in 1930. Hamburg has relatively the greatest number of hospital beds. Until 1929 the number of patients constantly increased, but in 1930 for the first time a decrease was recorded. Reasons of the decrease are (1) the lessened incidence of illness, especially of influenza, and (2) the economic situation which compels patients, particularly those belonging to the Krankenkassen, to keep out of hospital as long as possible. The largest call on hospital beds is made by cases of injury. Injuries of the skull, the vertebral column, and the pelvis have become more frequent owing to the rising number of severe motor-car accidents. Diseases of the female sexual organs, abortions, and tuberculosis have considerably increased too, and so has appendicitis, where fortunately the mortality is only one-third what it was before the war. Diabetes and gastric ulcer have increased, enteric fever and venereal diseases diminished. Circulatory troubles have become more frequent, inasmuch as the average age of the population has become higher since the war.

REMOVAL OF THE SPLEEN

Prof. Mühsam, chief surgeon to the Virchow Hospital in Berlin, writes that up to 1894 only 121 cases of splenectomy were recorded, but that the indication for that operation was then greatly extended when it was ascertained that certain blood diseases—e.g., leukæmia, Banti's disease, and thrombopenia—were cured or improved by it. He has himself performed splenectomy for ruptured and migrating spleen, for aneurysm of the splenic artery, splenic abscess due to embolism or complicating enteric fever, tuberculosis, and echinococcic cysts. In syphilis splenectomy is indicated if antisyphilitic treatment has been unsuccessful and pain is severe; in malaria, too, it may be necessary to relieve the pain of an enormously enlarged spleen. Pernicious anæmia is, he thinks, no longer an indication for splenectomy since liver therapy has proved so successful. Of 60 splenectomies of his own 29 were cured and 31 died.

UBIQUITY OF PFEIFFER'S BACILLUS

Dr. Gundel and Dr. Linden, as a result of investigations at the hygienic institute of Heidelberg University, find Pfeiffer's bacillus in all kinds of acute disease of the respiratory organs in non-epidemic periods. In younger children the presence of the bacilli is transitory, but older children and adults carry them longer than do actual cases of influenza. The bacillus lives as a saprophyte on mucous membranes, becoming virulent when the resistance of the organism is diminished.

THE CURABILITY OF SARCOMA

Dr. Hintze lately read a paper before the Berlin Medical Society recording 678 cases of sarcoma attended in the University surgical clinic during the last 18 years; of these 214 were still alive after five years. This success was due in one-third of the cases to operation and in two-thirds to radiotherapy. Cases in which an operation was done without radiotherapy were successful in 28·7 per cent.; with radiotherapy combined with operation the percentage was 33·2. The best results were recorded in cases where prophylactic irradiation was performed, the number of cures being 39 per cent. The choice of operation or radiotherapy, or both combined, depends on the position of the growth. In sarcoma of the mamma and of the extremities amputation followed by irradiation is indicated. In sarcoma of the hypophysis, tonsils, pelvis, and spleen, and in malignant lymphoma, cures were obtained by radiotherapy only. No test excision ought, he thinks, to be made without a following application of rays. Chances of cure increase with improvement of technique and greater experience.

In the Reich only eight leprous patients are registered. One new case from abroad was conveyed to the medical clinic of Giessen University; one case has left the country and one has died. So that the number is now only seven.

PUBLIC HEALTH SERVICES

Defective Vision in School-children

At the present time the method used to detect visual defects in school-children is a test of visual acuity; children who read 6/6 or 6/9 are passed as normal, others are referred for testing by refraction. In addition, a certain number of children are tested by refraction because of squint or of such symptoms as migraine, blepharitis, conjunctivitis, and headache. Dr. A. A. Douglas, school oculist for Ealing, suggests that this method has certain drawbacks, the chief of which is that many cases of defective vision are not detected by it. Thus many children with hypermetropia, even of high-grade hypermetropia, go uncorrected. More important, cases of early myopia and astigmatism are not submitted for refraction until some diminution in visual acuity of vision calls attention to them. The committee of inquiry into problems connected with defective vision in school-children found that in unselected children the percentages were:—

Simple myopia ..	2·4	Mixed astigmatism ..	1·2
Myopic astigmatism ..	0·8	Simple hypermetropia ..	64·2
Hypermetropic astigmatism	13·9	Emmetropia	5 8
		Anisometropia ..	11·7

If these percentages are applied to the total number of school-children in a locality the expected number in each of the groups can be compared with the actual number on the records of the school oculist, correction being made for the children (estimated at 10 per cent. of the total) who receive ophthalmic treatment privately. Taking the total number of school-children in Ealing as 12,100, Dr. Douglas finds the expected and actual numbers of the more important refractive abnormalities to be these:—

	Expected.	Actual.
Simple myopia..	298	118
Myoptic astigmatism	94	45
Hypermetropic astigmatism ..	1696	235
Mixed astigmatism	100	75

It is rather disturbing, he says, to find that the actual numbers of children with myopia and myopic astigmatism fall so far short of those expected. Doubtless, many of the undetected cases are slight, but these are just the cases it is important to detect, and the findings support the inquiry committee's view that the practice governing ophthalmic work in schools needs modifying. The difficulty is to decide on a suitable reform. To test every child by refraction would result in expenditure that could not be entertained for the present. The efficiency of routine examination could be improved by such simple procedures as testing acuity with a +1 D. lens —the eyes of all school entrants might be thus tested as soon as they know their letters; children with symptoms which might be due to an uncorrected refractive error should be examined by refraction.

Myopes Dr. Douglas divides into three groups: (1) Those who can see well and have no severe or progressive defect. These are the larger number (nearly 70 per cent.), and they can follow the ordinary curriculum. (2) Those who have a moderate defect in both eyes or a serious defect in one eye only. These are fewer in number (about 20 per cent.); they can do modified school work with reasonable precautions. (3) Those with severe or rapidly progressive defects. Their number is smaller (11 per cent.); some of them cannot read ordinary type. The second, and especially the third group, cause the difficulties, the more so because scientific opinion is divided on the value of the measures adopted. The majority of ophthalmologists in this country believe that the morbid process is accelerated by ordinary school work, and that homework should be prohibited. The opposing school holds that the progress of the disease depends on hereditary and constitutional factors. If this latter view is correct, as it may well be, to prohibit such children from reading is to take a serious responsibility. To deprive an intelligent child of 12 of books at the time when normally he starts to acquire those habits of curiosity and study upon which so much depends later may well be resented by parents. Myopes can rarely excel at games or sport, and to deprive them of their traditional consolation and path to a healthy self esteem may pave the way to a sense of inferiority. Dr. Douglas thinks the best course is to allow such children to attend the ordinary schools for part of the time and to devote the rest to special instruction.

Of the hypermetropes less than 20 per cent. had +3 D. or more; nearly all of these had diminished visual acuity. Those with less than +3 D. were often brought for refraction because of symptoms such as migraine, styes, conjunctivitis, or blepharitis. Why, it may be asked, should children who have the amount of hypermetropia normal for their years suffer from symptoms which can often be rapidly relieved by the wearing of glasses. Dr. Douglas suggests that in many cases hypermetropic astigmatism, too slight to be revealed by the method of classification used, is the real source of trouble.

Industrial Housing

The housing difficulties described by Dr. J. Yule in his report as medical officer of health for West Bromwich are typical of those met with in many industrial towns. Since the last census the population of the county borough has increased by 10,000, and the 82,000 residents are now accommodated in 18,500 houses, mostly of the working-class type. During the intercensal period the average number of persons per inhabited house has gone down from 4·9 in 1921 to 4·4 in 1931. The most serious difficulty is to meet the demand for additional houses at a rental suitable in the present state of financial stringency. Another difficulty is experienced in obtaining building sites within reasonable reach of the centre of the town, with inexpensive transport to the works. Much of the land in the borough is unsuitable for building purposes owing to mining operations. The activities of the corporation are indicated by the erection of 2816 houses since 1920; of these, 1816 are of the non-parlour three-bedroom type, 105 of the non-parlour two-bedroom type, and 834 and 61 of the parlour type with three and four bedrooms respectively. During 1931 the corporation erected 518 houses, the largest number in any year since the war, whilst only five State-aided houses were erected by other enterprise. As regards older houses, 8000 have two, three, or four rooms, including 1350 of the back-to-back type, and the majority of these are from 50 to 100 years or more old. A moderate estimate gives 1250 unfit houses. There are 7000 without adequate internal water-supply, and 6000 with no w.c. accommodation within their own curtilage. One unhealthy area has been dealt with and some progress has been made with three others during 1931. Miss A. J. Philipp, the housing manager, gives, as signs of the easing of the housing situation, the facts that applicants now frequently find other accommodation, while municipal tenants quit and obtain houses under private ownership, and many tenants are purchasing houses. On the other hand, the applicants now left on the register are the most difficult to help—namely, those who can pay a very low rent for accommodation near their work, and casual labourers, who cannot afford a whole house. A simpler type of house is needed and there is a long waiting-list for the houses on Friar Park Estate, let at an inclusive rent of 7*s.* 9*d.* to 8*s.* 9*d.* Miss Philipp pleads for shopping facilities and buildings for social functions on the outlying estates, and records that the first annual garden competition was a great success. She also reports that the tenants removed from the slums improve in the standard of cleanliness and behaviour beyond expectation, but that perhaps 10 per cent. have not the ability to raise themselves above their slum habits. The housing committee have therefore erected four experimental bungalows within easy distance of the town let at an inclusive rental of 6*s.* 6*d.* weekly, and it is hoped to erect others which can be let at an even lower rent.

Another experiment has been the transformation of a large de-licensed public-house into two flats in which two families of 15 members each are accommodated. Many tenants who could normally pay the rents of cheaper houses are handicapped by the need for paying weekly instalments on hire-purchased furniture, and to meet this the housing committee has an exhibit of amateur furniture, made entirely from packing-cases, borrowed from the Birmingham Copec House Improvement Society. By this method, it seems, a room can be entirely and satisfactorily furnished for 25*s.* The difficulties of the situation are aggravated by the increase of unemployment; the number of unemployed men in 1931 being 4480 as compared with 2956 in 1930.

MENTAL HOSPITAL REPORTS

At THE RETREAT, YORK, there were 189 patients at the end of last year; of the 103 admitted during 1931, 60 per cent. were voluntary and 9 "temporary." The death-rate was 11·6 per cent.; 33 patients were discharged recovered and 44 relieved. Dr. Neil Macleod, the medical superintendent, remarks that the admission-rate and type of illness seen show no reflection of the national crisis, and that the association of alcoholism with mental illness has been steadily decreasing in recent years. Special use is made in this hospital of glandular extracts, massage, ultra-violet rays, and organised occupation. The occupational therapy department, indeed, has grown so much that the instructor has been supplied with an assistant. There is a central pavilion, but a great deal of work is done in the wards as well. All the patients who were well enough went to a holiday house in the summer. Of the 106 male and female nurses, 53 are registered or certificated. The report makes cordial reference to the Final Report of THE LANCET Commission on Nursing, when discussing the problem of procuring suitable probationers. Dr. Macleod points out that there should not be any gulf between general hospital nurses and mental hospital nurses. The State register has a common entrance for all, and it is desirable, if not always practicable, that the mental nurse should have had a general hospital training. At The Retreat all the responsible nursing positions are held by doubly qualified women. The training school at The Retreat has a famous tradition, for the late Dr. Bedford Pierce was a pioneer in promoting the development of mental nursing, and Dr. Macleod shows that he is no less interested in the training of mental nurses.

The HERTFORDSHIRE COUNTY MENTAL HOSPITAL at HILL END, ST. ALBANS, had 972 patients in residence at the end of last year. The recovery-rate for the year was 36·8 per cent. and the death-rate 6·2 per cent. Various temporary expedients have been adopted to meet the demands for extra beds, and a number of mental defectives have been transferred to a colony; but the problem of overcrowding will arise again before long. There were eight cases of tuberculosis, two of dysentery, and one of chickenpox. Malarial treatment was used for three cases of general paralysis. A number of patients were seen at the dental, gynæcological, and ear, nose, and throat clinics, and radiological examination, where necessary, was obtained in the town. A large number of patients had their interest aroused by occupational therapy and physical drill classes. The work of the pathological laboratory is increasing, and examinations are made for other institutions in the county. During the year, 26 voluntary and 8 temporary patients were admitted. An out-patient clinic has been established at the St. Albans and Mid-Herts Hospital. Parole beyond the estate was granted to 21 men and 82 women, and 48 men are free within the grounds. The search for nasal sepsis as a cause of mental disorder has proved disappointing, but tonsillectomy has been useful. During the year nine nurses and two attendants obtained R.M.P.A. certificates.

At the LEICESTER AND RUTLAND MENTAL HOSPITAL there were 783 patients at the end of last year. The recovery-rate for the year was 35·3 per cent., and the death-rate 9·5 per cent.; the causes of death were verified by post-mortem examination in 87·6 per cent. of cases. Apart from three cases of Flexner Y dysentery, the general health was good. During the year 21 voluntary patients and 1 temporary case were admitted; the average duration of stay of the voluntary patients was two and a half months. Overcrowding has now reached alarming proportions, but 40 quiet cases are to be transferred to public assistance institutions. The laboratory has made over 1000 examinations. During the year three attendants and six nurses obtained R.M.P.A. certificates.

The DOWN COUNTY MENTAL HOSPITAL at DOWNPATRICK publishes a report illustrated with photographs of its operating theatre and the X ray, hydrotherapy, and occupational therapy departments. There were 826 patients on the books of the institution at the end of 1931. The recovery-rate for the year was 32·6 and the death-rate 7·3 per cent. The hospital is on the verge of overcrowding, but the new male occupational therapy department made possible a rearrangement whereby 15 new beds were provided. A number of patients have been granted parole. The most notable event in the history of the year was the completion of the hydro-electric department; two consulting radiologists and a radiographer have been appointed. There were nine cases of zymotic disease, of which the source could not be traced. Some 60 per cent. of the patients are usefully employed. Four nurses passed the R.M.P.A. examination, bringing the total number certificated up to 70.

At BARNWOOD HOUSE, GLOUCESTER, there were 223 patients at the end of last year: 1 temporary and 20 voluntary. For the first time in the records of the hospital the numbers of certified and voluntary patients admitted were practically equal. The recovery-rate was 50 per cent. of the admissions and the death-rate was 9·87 per cent. The general health was good, but many of the cases admitted were elderly and debilitated. One patient suffering from general paralysis was treated with malaria and was discharged recovered. Several patients suffering from dementia præcox were also treated, but without improvement. All new patients have a routine examination by the pathologist. The value of occupational therapy has again been demonstrated, and the medical superintendent shows that different types of mental disorder require different kinds of occupation. The summer house at Weston-super-Mare was again much appreciated. An X ray apparatus has been purchased and a dark room fitted up; nearly all new patients have their teeth X rayed. Dental films are sent to a dentist and other films to a radiologist for interpretation. During the year 12 nurses passed the final examination of the R.M.P.A.

bringing the total certificated to 85 per cent. of the men and 45 per cent. of the women.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED SEPT. 10TH, 1932

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 9 (last week 10); scarlet fever, 1389; diphtheria, 796; enteric fever, 79; acute pneumonia (primary or influenzal), 398; puerperal fever, 44; puerperal pyrexia, 89; cerebro-spinal fever, 28; acute poliomyelitis, 33; acute polio-encephalitis, 8; encephalitis lethargica, 16; relapsing fever, 1 (Uxbridge); dysentery, 40; ophthalmia neonatorum, 83. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Sept. 13th–14th was as follows: Small-pox, 19 under treatment, 2 under observation (last week 20); scarlet fever, 1113; diphtheria, 1286; enteric fever, 14; measles, 344; whooping-cough, 391; puerperal fever, 25 (plus 10 babies); encephalitis lethargica, 232; poliomyelitis, 4; "other diseases," 109. At St. Margaret's Hospital there were 12 babies (plus 9 mothers) with ophthalmia neonatorum.

Deaths.—In 117 great towns, including London, there was no death from small-pox, 3 (1) from enteric fever, 12 (0) from measles, 5 (3) from scarlet fever, 20 (2) from whooping-cough, 22 (6) from diphtheria, 89 (29) from *diarrhœa and enteritis under two years,* and 9 (3) from influenza. The figures in parentheses are those for London itself.

The deaths from diarrhœa were 14 more than in the previous week, the highest figures being Liverpool 16, Leeds 6, West Ham 4, Southampton 3. The fatal cases of enteric fever outside London occurred at Luton and Grimsby. Three of the deaths from measles were reported from Wigan. Diphtheria accounted for 4 deaths at Hull, 3 at Liverpool. The number of stillbirths notified during the week was 253 (corresponding to a rate of 40 per 1000 total births), including 38 in London.

PANEL AND CONTRACT PRACTICE

Questions of Mileage

THE North Riding insurance committee has decided to send a deputation to the Ministry of Health to ask for a special mileage grant to doctors in practice in that area. Rural practitioners are allowed £250,000 to pay for mileage, and it is the duty of the distribution committee to advise the Minister how this sum should be divided up. At present the grant does not apply to attendance on insured persons who live within two miles of the doctor of their choice; one unit of mileage is allowed for a patient living under three miles but over two miles away, two units for one living under four miles but over three, and so on. Quite recently all rural practitioners were requested to revise their mileage lists in order that each insurance committee might report to the Ministry, and so to the distribution committee, their claim for so many units. The £250,000 is divided up amongst these total units, each committee being allocated a sum to cover the mileage claim of each practitioner. The matter does not however rest there, for in addition to the claim for ordinary mileage (which suburban practitioners do not obtain), rural practitioners can claim a special mileage allowance if they have patients who live in places difficult of access—say, the Lake district or the Highlands. A sum of £10,000 can be drawn on for this purpose and, presumably, North Riding doctors could put in a similar claim. It has always been doubtful whether the rural practitioner was adequately recompensed for his extra costs, both in time and in wear and tear on car, for attendance on an insured person living (say) four miles away, if at the end of that journey he had to walk through places impossible for a car to pass in winter; and extra payment could probably be claimed for such a case. But the suggestion that an insurance committee might pay less mileage rates to some doctors in order to pay more to others is contrary to present regulations, and could not be realised without an alteration of the regulations after negotiation with the Insurance Acts Committee. If the deputation to Whitehall can do anything to settle the rural practitioner's grievance the journey will not have been made in vain.

Compensation Law

The fact that a patient has had an accident at work—for which, presumably, he will obtain compensation—does not do away with the obligation of an insurance practitioner to give him weekly, if he asks for it, the certificate of incapacity. The practice of approved societies in the matter varies. Some insist on the weekly certificate and others do not ask for more than a final certificate after they have received notification of the accident. The use of these weekly certificates is to excuse contributions under the Act, so that the member does not get into arrears through incapacity, the result of accident. The *National Insurance Gazette* of Sept. 10th discusses the case of an injury at work resulting in the loss of an eye, in which the employers called an eye specialist, who said that after about six weeks' work a man with one blind eye might be just as competent a mechanic as a man with two sound eyes. The judge is reported to have remarked that if all the eye surgeons in the world said that a one-eyed man was as good as a man with two eyes he would not have believed it. The workman must prove total or partial incapacity to sustain a claim for payment or continuance of payment of compensation, and in this case the question of disfigurement arises. If through disfigurement the patient is unable to obtain work he is entitled to compensation, but if disfigurement does not give rise to incapacity or cause difficulty in securing employment there is no provision in the Act for payment of compensation—a difference from the common law, where damages may be claimed for disfigurement resulting from an accident due to negligence in addition to loss of wages. Again, a workman is not entitled to compensation solely for the loss of an eye, irrespective of whether he can follow his old employment or not. He has to prove incapacity, either total or partial, and the requirements of the law are illustrated by the following words of the county court judge:—

> "In my view it is inadvisable that the applicant should resume work as a guillotine cutter or attend to machinery for the present, but I find that by the beginning of November, 1930, at the latest, he was fit to do work as a labourer or roundsman or storekeeper, or in fact any work not calling for strict accuracy of vision, and that as from that date he was capable of earning a weekly wage at least as high as that earned by him in the employment of the respondents. His failure to find such work was not due to the fact that he had become a one-eyed man."

The custom of many insurance companies is to try, after a certain period has elapsed, to settle a claim for some lump sum. This has given rise to the opinion amongst workmen that companies must compensate for the definite loss of an eye, regardless of incapacity or capacity to work. The above statement quite clearly shows this not to be the case.

CORRESPONDENCE

THE INCREASE IN ARSENIC-RESISTANT SYPHILIS

To the Editor of THE LANCET

SIR,—Dr. Browdy has not quite understood me. In the treatment of early syphilis, the first essential is to have a satisfactory and attainable standard of cure. The aim of therapy is to reach that standard in the shortest possible time, with the smallest amount of therapy, and without causing any damage to the patient. Furthermore, this standard must, from the treatment given, be attained by *every* patient. For example, the course of treatment laid down for a case of early syphilis must be such that if it is completed according to schedule, that patient will undoubtedly pass the tests of cure adopted. That is what is meant by a 100 per cent. cure-rate.

While it is impossible to tell with absolute certainty, in the living, if or when every *Treponema pallidum* has been destroyed, nevertheless experience has shown that if certain tests are fulfilled, cure of the disease may be assumed. In my view the minimum standard of cure consists of :—

(1) Negative Wassermann and two other supplementary tests—such as the Kahn and Meinicke—on the blood after provocation, carried out every 12 weeks for at least two years after the cessation of treatment.
(2) Negative cerebro-spinal fluid tests during these two years.
(3) Absence of clinical and radiological signs.

Patients who have passed these tests, and even others which are less severe, have not relapsed in after-years; some have got married with safety to their partners and to their progeny; and a few have even acquired an undoubted second infection. It may, then, be taken that such tests are sufficiently stringent; and that when they are fulfilled, they indicate that such patients have been cured by the treatment administered.

Assuming for the moment that these criteria are accepted—in other words, that unless patients are subjected to these tests and pass them they cannot be considered cured—then the lower limit of adequate treatment consists of the minimal amount, intensity, and duration of therapy with which they can be attained. The damage wrought by syphilis depends upon three main factors: (1) the virulence of the parasite; (2) the resistance of the host to the disease; and (3) his power of reacting to the remedial agents given. It is therefore very clear that there must be a wide margin between the degree of therapy which will cure the mildest infection in the most favourably reacting patient, and that which will be efficacious in a virulent case, where the patient responds in a slow and unsatisfactory manner. And it is important to note that it is impossible to say when the patient is seen if the disease is a mild or a severe infection, and whether or not the response to treatment will be sufficient. Since, upon the criteria of cure adopted, it is possible to attain a cure-rate of 100 per cent., it naturally follows in order to reach this, that mildly infected persons, those who are endowed with a high degree of resistance to the disease, and those who respond well to remedial agents, must most certainly be over-treated if they are in receipt of a degree of therapy necessary to cure less fortunate persons. As it is impossible to tell into which category a patient will fall, the fact must be accepted that in order to cure *all* patients, a certain proportion must inevitably receive treatment after all the treponemas have been destroyed. It is therefore essential that therapy be of such a kind that administration in excess of what is absolutely necessary for sterilisation shall not of itself cause any damage to the patient. This is the reason why drugs with high chemotherapeutic indices should be chosen. Such agents can be exhibited in an amount and with an intensity far in excess of what is necessary for sterilisation, without inflicting any bodily damage.

Under-treatment is a very serious matter—probably more so than no treatment at all. To be sure that all patients have adequate treatment—i.e., to reach a cure-rate of 100 per cent.—implies an equal certainty that many must receive more medication than is strictly necessary. This, however, need not be harmful. It is possible that to some patients suffering from sero-negative primary syphilis, even eight weekly intravenous injections of neo-arsphenamine would be over-treatment. A few rare cases may actually be cured by four such injections at intervals of three weeks with or without hyd. c. cret. by mouth. But it is quite impossible to tell what cases will be cured by such trivial therapy; and if they are uncured, the disease is digging itself into their viscera during the time they are being tested. Their last state is thus worse than the first.

To be sure of giving adequate therapy to *every* patient, over-treatment for a certain number is both unavoidable and expedient. Even what has been termed "gross over-treatment" need have no noxious effect. The term "over-treatment" is not a good one, since the suggestion contained therein is that remedial applications beyond the stage of sterilisation—which stage is not identifiable at once—is harmful. It is perhaps immediately uneconomical, but it need not be deleterious. If therapy is pushed so that the patient suffers, that is not over-treatment but *bad* treatment. The fear of giving more of a drug than is necessary, of continuing with it beyond the time when cure has been effected, is a bogy. It would be a harmless one were it not for the fact that its presence causes the pendulum to swing too far in the other direction and so result in under-treatment. That is a matter for grave concern.

The point I am anxious to make is that by a careful analysis of case-records, every syphilologist should be able to say what is the minimum course of therapy which he finds attains a cure-rate of 100 per cent. in early syphilis. If his course does not attain that result, then it is inadequate. I will give one instance out of my experience :—

In sero-negative primary syphilis by giving neoarsphenamine (9·25 g.) and bismuth (3·2 g. of the element in the form of a suspension of the metal in isotonic glucose) during a period of 24 weeks according to the alternating principle which I adopt, every case without exception over an observation period of never less than two years, has suffered no clinical or serological relapse. For late primary, early secondary, and late secondary cases, slightly longer courses are used, but the results are identical—a cure-rate of 100 per cent. Since the beginning of 1931 the courses have been increased in duration by two or three weeks each, so as to give higher efficiency indices and to allow a little more latitude for irregular attendance.

There is nothing out of the ordinary in these results. A great many other workers get equivalent results from other methods. The point is that all such courses have one thing in common which can only be designated "adequacy," but which has been a difficult thing to measure. It is impossible to compare different methods occupying different times and using different drugs unless there can be found some "yard-stick" which can be applied to all. By utilising the chemoherapeutic indices of the agents, and from these, llotting to each drug a therapeutic unit value, a ormula has been found which takes into account he variable and vital time-element, and enables one o arrive at an index figure representing the quality r efficiency of the therapy. By this means the fficiency indices of a large number of different courses s used in Great Britain, Europe, and the United States, have been worked out; and this fact emerges: hat wherever a cure-rate of 100 per cent. is obtained, he efficiency index is 70 or over. For example, hat at St. Thomas's Hospital in London is 81; that quoted by Hazen, based upon the methods at the Johns Hopkins and Mayo Clinics, and set out as the "ideal" course, gives an index of 90. I therefore say, without any hesitation, that—to take again the case of sero-negative primary syphilis—the minimum duration of treatment must not be less than 24 weeks, and during that time sufficient therapy must be given so that the efficiency index does not fall below 70. Anything below that is inadequate in so far as 100 per cent. of cures is concerned; adequacy is represented by 70 or over.

Dr. Browdy asks: "Is it not preferable to have a working basis of treatment and to treat individuals as necessity demands?" It is not merely preferable; it is *essential*. Necessity demands that every individual must be treated upon the assumption that the infection is severe, and that he is a person with low resistance and a poor therapeutic response. The therapy applicable to that condition is that which has at least 70 points of efficiency. Such is the only sure working basis of treatment. It is easily put to the test; and if it were in any way found wanting, there would be no undue delay in hearing about it.

I am, Sir, yours faithfully,

E. TYTLER BURKE.

City of Salford Municipal Clinic, Sept. 10th, 1932.

PATHOGENESIS OF CAVITIES IN THE LUNGS

To the Editor of THE LANCET

SIR,—The interesting article by Dr. J. Sowerbutts in your issue of Sept. 17th (p. 623), describing an annular shadow which caused "bulging" of a collapsed lung, has again raised several controversial points concerning the pathogenesis of pulmonary cavities. Dr. Sowerbutts inclines to the theory put forward by W. Mitchell, who looks on these rings as air cysts following perforation of a bronchus and the escape of air into the interstitial tissue of the lung. This theory is satisfactory in so far as it explains the relatively sudden occurrence and disappearance of these definitely intrapulmonary shadows; but is it not a little far-fetched to assume that air passes through the bronchial wall, giving rise to a single bubble or cyst instead of an interstitial emphysema?

It seems more probable that these thin-walled cavities arise in the alveolar tissue in a similar manner to emphysematous bullæ. One of the fundamental facts of pulmonary physiology is the relative difficulty of expiration as compared with inspiration. Not only is the lumen of the bronchus smaller during expiration, but the presence of any partial obstruction such as tenacious secretion or thickened mucous membrane tends to produce a valvular action. During the deep inspiration following a cough air will be sucked through a partially obstructed bronchus and will have difficulty in returning during the expiratory phase. Should the alveolar walls in any region be weakened by disease it is easy to see how an air cyst could arise in the parenchymatous tissue of the lung.

Vere Pearson has observed [1] that when a pneumothorax needle was introduced into a large cavity a positive pressure was found: this recurred after it had been reduced by aspiration of air as soon as the patient took a few deep breaths. Pearson's observation points to the presence of a valvular mechanism even with a large chronic cavity; this might result from partial obstruction of a bronchus, or even from the presence in the cavity of fluid too thick to pass through a bronchus although still allowing bubbles of air to be sucked through it during forced inspiration.

The fact that many cavities, particularly when rapidly formed, are round in outline, also suggests the presence of air under pressure, and I submit that in their pathogenesis the most important factor is some valvular action in the smaller bronchial tubes which, by interfering with the escape of air from the damaged alveoli, causes the lung to pump itself up and thus produce cavities. Removal of the obstruction would explain the occasional rapid disappearance of the annular shadow.

I am, Sir, yours faithfully,

ANDREW MORLAND.

Mundesley Sanatorium, Sept. 18th, 1932.

LONGEVITY OF ANTHRAX SPORES

To the Editor of THE LANCET

SIR,—In the course of my work I have found an interesting fact regarding the length of life of the anthrax bacillus. Having noted that old dried-up cultures of anthrax spores still survived after having been stored in glass jars for just over two years, I kept agar cultures for longer periods, the oldest of which was made in January, 1914. To these old cultures, which resembled a small streak of horn-like substance, some sterile broth was introduced, and they were incubated at 37° C. for two days. All the tubes then exhibited the typical appearance. The growth in the oldest one was subcultured and examined microscopically; it showed a pure culture of *B. anthracis*. Thus the spores had survived after having been stored away for eighteen and a half years.

I am, Sir, yours faithfully,

W. H. LAUNDER,
Bacteriologist to Jeyes Sanitary Compounds Co.

Sept. 17th, 1932.

SAFE MILK

To the Editor of THE LANCET

SIR,—The matter of safe milk is important professionally as well as intrinsically; doctors are continually asked for practical advice. But with such conflicting guide-posts as the following what course can we steer?

(1) A leading article in your issue of Sept. 10th (p. 581) states: "We know that 6·4 per cent. of the mixed milks of this country contain living tubercle bacilli."

(2) Dr. Roodhouse Gloyne recently published investigations in *Tubercle* which showed that 10·2 per cent. of samples of Grade A milk, and 3·8 per cent. of samples of Grade A (T.T.) milk were contaminated with tubercle bacilli.

(3) The Manchester city council found 2·2 per cent. of pasteurised milk samples were positive to tubercle bacilli. (*Medical Officer*, 1932.)

In the light of these statements from responsible sources it would appear: (*a*) there is no absolute safety anywhere; (*b*) ordinary mixed milk comes out better than Grade A; (*c*) the more expensive type—Grade A (T.T.)—appears as rather less safe than pasteurised. We are thus led up to the position taken by the Ministry of Health that both the Grade A (T.T.) ritual, and also pasteurisation, are desirable if *security is really sought.*

---

[1] Brit. Med. Jour., 1930, i., 381.

The "drink more milk" campaigners will come off badly if all this is realised. Already the medical officer of health for Lewes, writing in the *Times* (Sept. 15th), is suggesting that the proportion of samples in which tubercle bacilli are found "raises the question whether the provision of Grade A (T.T.) milk to school-children, as adopted by many of our education committees, is altogether free from risk."

I am, Sir, yours faithfully,
ESTHER CARLING.

Berks and Bucks Joint Sanatorium, Sept. 16th, 1932.

ANAPHYLAXIS FROM BEE STINGS

To the Editor of THE LANCET

SIR,—In those stung by bees severe symptoms are not uncommon. They may include faintness, pallor and cyanosis, diarrhœa, urticaria, unconciousness and, exceptionally, death within a few minutes, yet text-*books seem to be completely silent on the* subject. I recently had a case of a labourer, aged 69 years, who died five minutes after being stung by a bee on the back of the neck. A week previously he had been stung on the top of the head without any ill-effects; but four years before he had been unconscious for some hours and unable to work for three weeks following a sting (location unknown). ' Is this idiosyncrasy a form of protein shock; or does it depend, as Dr. Ryle has suggested,[1] upon the entry of the poison into a superficial vein ? I am told that the bee has both acid and alkali poison glands; are they both used, and why, and when ?

I am, Sir, yours faithfully,
NEVILLE M. GOODMAN, M.B.

Lymington, Hants, Sept. 19th, 1932.

---

MEDICAL NEWS

University of Birmingham: Faculty of Medicine

On Tuesday, Oct. 4th, the distribution of medals and prizes will take place in the medical lecture theatre, and an address to students will be given by Prof. J. T. J. Morrison, F.R.C.S.

Harveian Society of London

The programme of the first half of the session has now been issued. On Nov. 13th Sir Harold Gillies will give a lantern and cinematograph demonstration of plastic surgery at the Hammersmith Hospital, Ducane-road. On Nov. 9th Prof. Grey Turner will give a surgical lecture, under the title Nil Desperandum, at Paddington Town Hall, and at the same place on Dec. 8th Dr. Macdonald Critchley will open a discussion on Migraine.

Institute of Hygiene

A series of lectures will be delivered in the Lecture Hall of the Institute, 28, Portland-place, London, W.1, on Wednesdays, Sept. 28th to Dec. 14th, at 3.30 P.M. Prof. Samson Wright will give the first lecture on Sept. 28th, on Diet and Dietetics, Dr. J. Browning Alexander presiding. Subsequent lectures in October will be: Some Everyday Aspects of Goitre, by Mr. A. E. Mortimer Woolf; the Prevention of Rheumatism in Industry, by Dr. W. S. C. Copeman; Obesity and Slimming—their Cause and Effect, by Dr. Gerald Slot; and the Hygiene of the Ear, Nose, and Throat, by Mr. C. Hamblen Thomas. The lectures are free to men and women interested in health problems.

Public Health Congress, 1932

This congress, of which Sir Hilton Young is the president, will be held at the Royal Agricultural Hall, London, throughout the week commencing Nov. 14th. On Nov. 18th, at a meeting under the auspices of the British Hospitals Association, a discussion on the Report of THE LANCET Commission on Nursing will be opened by the Editor of THE LANCET, Sir Arthur Stanley presiding. The provisional programme includes also the following: a paper on Housing and Slum Clearance, by Dr. C. Killick Millard; a discussion on the Scope, Uses, and Abuses of Infant Welfare Centres; a paper on Smoke Abatement and Public Health, by Dr. H. A. des Voeux, and one on Fumes Emission from Road Vehicles, by Dr. J. S. Owens; papers on Occupational Therapy in Mental Hospitals and Industries in Mental Deficiency Colonies, respectively by Colonel C. F. de Salis and Captain C. W. Mayer, Mr. L. G. Brock presiding; a communication on the Economic Value of Physical Treatment, by Dr. J. B. Mennell; a discussion on the Contribution of Hospitals to Preventive Medicine, to be opened by Mr. C. E. A. Bedwell, Sir Arthur Newsholme presiding; a discussion on the Position of the Poor-law Institution in Relation to National Life, to be opened by Mr. C. A. W. Roberts; and one on the Correct Use of Heat Rays for Producing Comfort in Living Rooms, to be opened by Sir Leonard Hill, Sir Francis Goodenough presiding.

SIR STCLAIR THOMSON has been granted His Majesty's Royal licence and authority to wear the Cross of Commander of the Legion of Honour, which has been conferred upon him by the President of the French Republic, in recognition of valuable services rendered by him.

DR. V. S. HODSON has been elected master of the Mercers' Company.

Manor House Industrial Hospital

This hospital has purchased Ivy House, North End-road, Golders Green, formerly the residence of the late Madame Pavlova, for use as a women's department.

Instruction in Hospital Administration

Two 3-months' courses of lectures and demonstrations on clinical practice and hospital administration will be given on Mondays and Wednesdays at 9.30 A.M. and alternate Saturdays, beginning on Monday, Oct. 3rd, respectively at the North-Western Hospital, Lawn-road, Hampstead, N.W.3, by Dr. A. Joe, and at the Brook Hospital, Shooter's Hill, Woolwich, S.E.18, by Dr. J. B. Byles. The courses are available for candidates for the diplomas in public health. Further particulars may be obtained from the Medical Officer of Health, London County Council, Public Health Department (Special Hospitals), the County Hall, S.E.1.

National Council for Mental Hygiene

A series of lecture-discussions on Mental Hygiene in Everyday Life will be delivered at the house of the Medical Society of London, 11, Chandos-street, Cavendish-square, London, W., on Wednesdays, at 5.30 P.M., during October and November. The programme is as follows:—Oct. 12th: The Inferiority Complex, by Dr. Henry Yellowlees; 19th: Guilt, by Dr. Mary R. Barkas; 26th: Rationalisation, by Dr. William Brown; Nov. 9th: Conflict and Character, by Dr. E. Graham Howe; 16th: Day Dreams, by Dr. Isabel G. H. Wilson; 30th: Envy, Hatred, and Malice, by Dr. R. G. Gordon.

Under the joint auspices of the Council and the British Social Hygiene Council a series of four lectures, illustrated by films, on Sex Education and the Child will be held at the May Fair Hotel, Berkeley-street, W. 1, on consecutive Tuesdays at 11.15 A.M., beginning on Tuesday, Oct. 11th. The lecturers will be Mr. D. Ward Cutler, Miss Muriel Bond, M.Sc., Dr. Elizabeth Sloan Chesser, and Dr. William Brown.

Royal Institute of Public Health

The Harben lectures will be delivered in the lecture hall of the Institute at 23, Queen-square, London, W.C. 1, by Dr. Max Neisser, professor of bacteriology and hygiene at the University of Frankfurt, on Some New Investigations Regarding Old Bacteriological Problems, on Oct. 10th, 11th, and 12th, at 4 P.M. The first lecture will be on Constancy, Variation, and Transformation of Bacteria, the second on Tubercle-like Acid-fast Bacilli, and the third on the Bactericidal Effects of Silver. A course of eight lectures on Preventive Medicine: The Maintenance of Health and the Avoidance of Disease, will be delivered at the same place at 4 P.M. on Wednesdays, starting on Oct. 19th, when Sir Ernest Graham-Little will speak on Preventive Medicine and the Education of Public Opinion, Sir Basil Blackett presiding. A course of six lecture-discussions on Mental Defectiveness as a Medico-Sociological Problem will be held at the Institute at 4 P.M. on Thursdays, beginning on Oct. 27th. The first subject will be Mental Defectiveness; Medical and Social Considerations, which will be considered by Prof. R. J. A. Berry, with Mr. C. J. Bond in the chair.

All these lectures and discussions are free.

OBITUARY

SIR CHARTERS SYMONDS, K.B.E., M.D.Lond., F.R.C.S.Eng., LL.D.

Sir Charters Symonds, consulting surgeon to Guy's Hospital, died at Mount Park, Harrow, on Sept. 14th, aged 80 years. His death removes a notable surgeon and teacher, whose life and example have left their mark on his time.

Charters James Symonds was born at Dalhousie, New Brunswick, in 1852. He came to London when he was 17 years old, and after passing the matriculation of London University entered Guy's Hospital, taking his M.R.C.S. in 1875. He won the Treasurer's gold medal in clinical surgery, and held consecutively the appointments of obstetric resident, house surgeon, and house physician. From 1876–79 he was a demonstrator of anatomy, and in the latter year he was appointed surgical registrar, having in the meantime obtained the M.B., B.S. Lond., with gold medals in surgery, obstetrics, and forensic medicine, and first-class honours in medicine, and the M.D. a year later. In 1880 he obtained the M.S. Lond. and in 1881 the F.R.C.S. Eng. While acting as registrar he utilised the opportunities of acquiring a wide and accurate knowledge of surgical pathology. He was appointed assistant surgeon to Guy's in 1882, and was placed in charge of the throat department, an appointment which he held for 20 years, until he was made full surgeon in March, 1902. From 1882–88 he was on the staff of the Evelina Hospital. In 1912, on retiring at the age limit from the active staff of Guy's, he was appointed consulting surgeon to the hospital. He held office in many medical societies, and was at different times president of the Hunterian Society, the Laryngological Society, the Medical Society of London, and the clinical and proctological sections of the Royal Society of Medicine. He was Lettsomian Lecturer in 1910, Bradshaw Lecturer in 1916, and Hunterian Orator in 1921. He was a member of the council of the Royal College of Surgeons from 1907–23, and vice-president in 1916. For some years before the war Symonds was a member of the Territorial Force, and in August, 1914, he was called up for military service; in 1915 he went as consulting surgeon to Malta, and in 1916 to Salonika, where he remained until he returned to England to serve in a similar capacity at Netley and in the Southern Command. In 1919 he was made K.B.E., having previously been given the C.B. and mentioned in despatches. In 1929 he received the hon. LL.D. of New Brunswick University.

SIR CHARTERS SYMONDS

[Photograph by Vandyk

Symonds started his surgical career at a time when the introduction of Listerian methods had just presented surgeons with great opportunities, and no one was better fitted than he for the pioneer work that had to be done. His sound knowledge of pathology, his power of accurate clinical observation, and his habit of scientific note-taking enabled him to see where progress could safely be made, and to avoid the mistakes that can so easily occur when enthusiasm outruns judgment. He had great courage, and would undertake any operation which his judgment led him to believe was in the best interests of the patient, but he never allowed his courage to lead him into recklessness. He was the first surgeon to do an "interval operation" for appendicitis; the patient, who was under the care of Dr. Mahomed, had had two acute attacks of appendicitis, and Symonds removed the appendix after the second attack had subsided. As a teacher of clinical surgery, he was unsurpassed, for he combined with great technical skill and sound clinical judgment the ability to state clearly the reasons upon which his decisions were based, and he kindled in his students an enthusiasm which he knew how to keep alive. One of them writes: "It was not only his own dressers and house surgeons that benefited by his teaching. His 'Monday round' at Guy's was for many years a famous institution, and attended by a large crowd, many of them post-graduates working for higher examinations. To all with whom he came in contact he showed a kindness and a courtesy that made him beloved by patients, students, and colleagues. He could always understand the difficulties of a beginner, and hundreds of his pupils remember with gratitude his patience and his encouragement."

After the close of the war Symonds continued to devote himself to the cause of humanity, and was president of the Invalid Children's Aid Association and treasurer of the Royal Medical Benevolent Fund. This fund lay very near his heart. He had long been a liberal subscriber before he joined the committee of management in 1908. After the death of Samuel West he was appointed hon. treasurer in 1917, and during an interregnum in 1927 he performed the duties of secretary for three months. He visited the office daily, and often spent many hours in making himself acquainted with the circumstances of individual applicants. In 1912 Symonds started paying fortnightly visits to Lambeth Hospital, where he continued to use his great gifts as a clinical teacher. These visits were interrupted by the war, but in 1920 they were resumed and continued regularly till within a few months of his death, long after he was aware of the mortal disease from which he was suffering. To the end he retained his wonderful memory of detail, and took the greatest interest in every advance that was made in surgery. It was characteristic of him that he bore his last illness with patience, and watched the progress of his disease with detachment.

In 1889 Sir Charters Symonds married Fanny Marie, daughter of Lieutenant-General David Shaw, of the Madras Army; she died in August, 1930. He leaves two sons, of whom the elder is physician in charge of the department for nervous diseases at Guy's Hospital.

T. H. C. STEVENSON, C.B.E., M.D. Lond., D.P.H.

Thomas Henry Craig Stevenson was born at Strabane, Co. Tyrone, in 1870, and educated at University College, London. He graduated as M.B. Lond. in 1896, later going on to the M.D. in State medicine and the D.P.H. Camb. He married, in 1900, Ella Louise, daughter of Mr. Samuel Sillifant, and left one son and one daughter. He served from 1905 to 1908 as assistant educational medical officer to the London County Council, and then for a short period as school medical officer in Somerset. In 1909 he was appointed superintendent of statistics in the General Register Office; and in that capacity, or under the substituted title of medical statistical officer which was introduced upon the augmentation of the professional staff of the department to cope with the expansion of its statistical functions, he served until his retirement in 1931 as a result of a breakdown in health. During the war he was a member of the reserved occupation and enemy personnel committees; and for these and other war services performed in the General Register Office he was created C.B.E. in 1918. He was a Fellow of University College, London; Fellow, Guy (gold) medallist, and formerly hon. secretary of the Royal Statistical Society, honorary member of the American Statistical Society, and Jenner medallist of the Royal Society of Medicine. Quite recently he was awarded the Bisset Hawkins gold medal by the Royal College of Physicians.

DR. STEVENSON

[Photograph by Elliott & Fry

But this bare chronicle of services and distinctions affords no indication of the real value of the work which Stevenson performed during his official career at the General Register Office. This must be measured, not only by the individual value of his many brilliant pieces of research, but by the less visible merit of his steady contribution to the maintenance and enhancement of those high standards of scientific sincerity and thoroughness stamped by Farr upon the work of the department. These services and the pre-eminent position which British vital statistics owe to them have already been described in terms which cannot be bettered. The occasion of Stevenson's retirement, hardly more than a year ago, was signalised by a letter of appreciation of his public work signed by six leaders of medical and statistical science. An independently framed appraisal of Stevenson's work could only echo less adequately and authoritatively the following extract:

"Of Dr. Stevenson's contributions to the scientific journals we shall say nothing, except that these would have sufficed to secure a permanent place for him in the history of statistical science. The searching and illuminating discussions of the problems of vital statistics which he has contributed to the Census reports and to the annual and decennial reports of the Registrar-General have formed noteworthy landmarks in the study of our national records. Dr. Stevenson's remarkable analysis of the data of the census of fertility taken in 1911 was a *tour de force*, while the essays contributed by him to the annual reports of the Registrar-General make a wider appeal and, in our judgment, place Stevenson second only to William Farr among those public servants who have secured for England her proud position in the realm of official vital statistics His studies of the factors of infant mortality, of the local distribution and evolution in time of mortality from tuberculosis and of the interpretation of the statistics of cancer mortality, especially in relation to its local incidence in the human body, are further examples of immensely important medical research. Dr. Stevenson first demonstrated, upon adequate data, the contrasting rates of mortality of single and married women from cancer of the breast and reproductive organs; this and his more recent studies of the variation of cancer mortality with social status constitute probably the most important statistical contributions yet made to our knowledge of malignant disease'

It is a melancholy reflection that this testimony, vouchsafed to the living man in grateful acknowledgment of a life work not then concluded, should so soon be invoked to serve as his funeral oration.

Mr. S. P. Vivian, Registrar-General, writes: "Stevenson possessed to a marked extent that curiosity which he himself insisted upon, when discussing after his retirement the qualities which he would like to see in his successor, as the most important element in the make-up of a successful researcher. He would 'browse' (the term acquired almost official currency as describing a recognised province of his official functions) upon the raw returns of the year's figures, observing, perhaps, some previously unnoticed movement which aroused his interest. Supplementary tabulations would be obtained, testing whether significance could be attached to the phenomenon; and if the result was positive, the hunt was up. In this way his holding office in a factory of statistics stood his research work in good stead; he had the earliest results under observation and could shape their tabular presentation with a view to their elucidating the special problems which engaged his attention at the time. It followed from his methods that, as he often confessed, he had not the slightest idea, before beginning to examine the year's figures, what subject he would select for special study in those sections of commentary for which he was responsible in the department's annual statistical review. He found it impossible, moreover, having noted a promising subject for examination, to put it into cold storage for resumption later; if the scent was hot, he had no choice but to follow it. The curiously easy style of his written work, making smooth the rough place of a complicated statistical exposition, was in marked contrast to his slow and halting habit of speech and apparent unreadiness in debate."

Some time may pass before Stevenson's work will be seen in its true perspective and with a full appreciation of its value to science and to the public welfare; his stature, like Farr's, cannot fail to increase with the lapse of years.

SIR HENRY SIMSON, K.C.V.O., F.R.C.S. Edin., F.R.C.P. Lond., F.C.O.G.

THE sudden and tragic death of Sir Henry Simson has come as a shock to most of his friends and patients, though those with whom he was intimately associated had been concerned about his health for ome time; although he was obviously not well he carried on uncomplainingly, and continued in full and active work until the end.

Henry John Forbes Simson was born in 1872 n India, being the son of Robert Simson, of the Bengal Civil Service, and Amy Inglis. He was educated at Edinburgh, passing from the Collegiate School to the University, where he graduated M.B., C.M., in 1895. He held resident posts at the Royal Infirmary, the Royal Hospital for Sick Children, the Royal Maternity Hospital, and the City Fever Hospital, and then travelled abroad for a year, spending much of the time in Egypt, before settling in London in 1900. The year before he had become F.R.C.S. Edin., and in 1901 he took the M.R.C.P. Lond., being elected F.R.C.P. in 1926. Simson's bent for obstetrics and gynæcology dated from his early days in Edinburgh, and was stimulated by the influence of Sir Halliday Croom, with whom he was at that time closely associated. In London he soon made a place for himself among those who practised his specialty, and for over 30 years had devoted himself to its development. His chief hospital posts were those of surgeon to the Hospital for Women, Soho-square—from the active staff of which he resigned three years ago, when he was appointed consulting surgeon—and of obstetric surgeon to the West London Hospital, which hospital he served also as dean of the post-graduate college. His aim was to provide adequate lectures, demonstrations, and practical classes for practitioners who sought revision courses in London, and he worked hard to this end. In connexion with both hospital and college matters Simson's opinion and advice were eagerly sought and generally acted upon, for his wisdom and good judgment were manifest in committee work. During the war Simson was consulting obstetrician to the Maternity Hospital for Officers' Wives, at 12, Princes-gate. He acted as examiner in obstetrics and gynæcology to the Conjoint Board and to the University of Leeds, and was one of the first Fellows elected to the College of Obstetricians and Gynæcologists, in the foundation of which he had played an active part. His professional association with the births of the children of the Princess Royal and of the Duchess of York gives him a claim on the gratitude of the nation; he was created K.C.V.O. in 1925. He married in 1908 the famous actress, Lena Margaret Ashwell.

SIR HENRY SIMSON

[Photograph by Bassano, Ltd

Simson was a clear and accurate thinker and was such a good listener that it was always a pleasure to talk to him. His activities were many; he was a man of great industry and yet did everything without fuss. His outstanding personal qualities were kindliness and sense of humour; he endeared himself to all who knew him. Simson made many friends and never lost any, perhaps because he never said anything to any man's detriment; it was foreign to his nature to think evil of anyone. When at school in Edinburgh he was distinguished as a three-quarter; he retained his interest in Rugby football and was often to be seen at Twickenham. He was a keen golfer, hitting a clean, long, straight ball with a 'follow through'; it has been said of him that his golf was typical of his conduct through life."

One who was associated with Sir Henry Simson for many years in hospital, and assisted him in his private work for over ten years, writes: "His charm of manner combined with great skill in obstetrics perhaps explains the extraordinary success of one who did not come to London until he was 28. What impressed me most in Simson as a colleague was his equable temperament. I saw him under every possible condition—he was as calm and collected under the most trying circumstances as when things were easy and straightforward. He never betrayed his feelings, although he was greatly troubled when a confinement or operation was not going well. His energy was amazing—only a man of magnificient physique could have worked as he did. After being up all night he would return home, take a hot bath, have breakfast, and start off again on a full day's work. His devotion to his work undoubtedly shortened his life. He was obliged to give up his ward at the Soho Hospital after a severe illness three years ago, but at the West London Hospital he never missed his ward visit or operating day if he could possibly help it. Simson's generosity was wonderful; he was always ready to help colleagues, friends, or patients, and he gave freely his professional services or his wise advice whenever these were called for."

IAN MACDONALD, M.D. Edin. and Paris

Dr. Ian Macdonald, whose death in London on Sept. 14th was briefly recorded last week, was born in Ballachulish, Argyllshire, where his father, a Free Church minister, died young, leaving a widow and two sons. There were no luxuries in his boyhood. Educated at the Royal High School, Edinburgh, he worked hard and played hard, becoming captain of the first XI. and XV. After graduating in medicine at Edinburgh in 1895 he went to the British Hertford Hospital in Paris as a resident medical officer learning there the principles of aseptic surgery and abdominal technique. As resident at the West Ham Hospital he saw many cases of burns, and wrote his thesis on picric acid treatment for the M.D. Edin. His next post was assistant medical officer at the Rio

DR. IAN MACDONALD

Tinto Mines, where malaria was then endemic. Laveran had found "bodies" in the red blood corpuscles, and the mosquito had been suggested as a "carrier." Macdonald had worked under Laveran, and, two months before Ross's great discovery, he had sent mosquitoes, fed on malarial blood, from Rio Tinto to Paris—but they died en route. On leaving Rio he joined his uncle, the late W. A. Mackay, at the British Clinic, Huelva, Spain, where he developed abdominal surgery to such effect that one of the main streets in that town is now named "Calle Macdonald." His contributions to surgical literature are to be found in the medical journals of England, Spain, and France; one of these recorded the results of 205 cases of gastro-enterostomy, another dealt with the prevalence of chronic gastric disease in Spain.

Of the man himself, Dr. Halliday Sutherland, his cousin, writes: "Seriousness was the main trait of his character. Everything he did, in work or recreation, he tried to do well. He was a first-rate angler and a fair shot. In tennis, golf, and cricket he studied the technique of the game. During holidays he watched the technique of other surgeons in France, England, and America. As he once remarked, 'They don't put everything in their books and articles.' He was modest, and with strangers had a grave and formal manner, but with intimate friends he showed a keen appreciation of humour. Over his cases he took great care in diagnosis and treatment; he was neither a bold nor a cautious surgeon, but operated with assurance, skill, and an eye which never overlooked the smallest detail in technique. His average time for a posterior gastro-enterostomy was 20 minutes, but he never hurried. He never wrote about a case until he had first read the literature. In conversation he was a good listener, but his critical faculty was always alert, and he had a keen appreciation of French, Spanish, and English prose. His stability and strength of character was best known to his relatives, who in times of sickness relied implicitly on his judgment."

In 1916 Dr. Macdonald married Elizabeth, second daughter of the late Peter Henderson, of Huntly, Aberdeenshire, who survives him.

THE SERVICES

ROYAL ARMY MEDICAL CORPS

Maj. D. T. Richardson, Asst. Prof. R.A. Med. Col., relinquishes his appt.

Maj. J. H. M. Frobisher retires on retd. pay.

Lts. (on prob.) R. Johnston and G. A. Kane are restored to the establishment.

Lt. E. Hicks resigns his commn.

INDIAN MEDICAL SERVICE

Lt. (on prob.) K. Jilani to be Capt. (prov.) (on prob.).

Col. L. P. Brassey retires, on account of ill-health.

ROYAL AIR FORCE

The undermentioned have been granted short service commissions as Flying Officers for three years on the active list: R. K. Muir, G. A. M. Knight, J. F. Ziegler, and F. H. Peterson.

DEATHS IN THE SERVICES

Lieut.-Colonel SANDFORD MOORE, who died on August 27th at Shankill, Co. Dublin, in his ninetieth year, was born at Forbes, Co. Longford, in 1843. In 1866 he graduated M.B. at Trinity College, Dublin, and as resident at Sir Patrick Dun's Hospital successfully nursed his colleague, S. M. Salaman, through an attack of typhus. This was the year in which cholera broke out in Dublin, and both residents offered to resign military commissions to remain on duty in the hospital. In the Franco-Prussian war of 1870–71 Moore served with the English Ambulance, receiving for his services both the Prussian war medal and the French bronze cross. He took part in the Ashanti war of 1873–74, and was present at Essaman. His experience in France led him to take an energetic interest in the treatment of the sick and wounded in war; he served on the central executive committee of the St. John Ambulance Association, and from 1882–86 was assistant professor of hygiene at Netley under F. S. De Chaumont. He also studied law and was called to the Bar. In 1887, being threatened with blindness, he retired with the rank of brigade-surgeon, being gazetted lieut.-colonel ten years later.

Medical Diary

Information to be included in this column should reach us in proper form on Tuesday, and cannot appear if it reaches us later than the first post on Wednesday morning.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

CHARING CROSS HOSPITAL POST-GRADUATE COURSE.

SATURDAY, Oct. 1st.—10 A.M., Mr. J. B. Banister: Uterine Inertia. 11 A.M., Mr. E. A. Crook: Some Practical Points in the Treatment of Rectal Diseases. 12 A.M. Mr. C. Jennings Marshall [illegible] Treatment of Chronic [illegible] Mr. A. C. Macleod: Mod[illegible] Oral and Some Other Ty[illegible] with a Short Review of [illegible] Dr. Gordon Holmes: The [illegible] Treatment of Sphincter Disturbance. 4 P.M., Dr. C. K. J. Hamilton: Common Disorders of the Urinary Tract in Infancy and Childhood.

SUNDAY.—10 A.M., Dr. F. H. Young: Pulmonary Suppuration. 11 A.M., Mr. W. H. McMullen: The Treatment of Some Common Ophthalmic Diseases in General Practice. 12 A.M., Mr. N. C. Lake: The Surgery of the Sympathetic Nervous System. 2 P.M., Dr. W. J. Adie: Neurological Lesions of Sudden Onset. 3 P.M., Dr. E. C. Warner: The Differential Diagnosis of the Principal Causes of Jaundice. 4 P.M., Dr. K. Shirley Smith: The Treatment of Heart Failure. (This course is open only to graduates and students of the school.)

KING'S COLLEGE HOSPITAL POST-GRADUATE COURSE.

SATURDAY, Oct. 1st.—2 P.M., Mr. Yates Bell: The Treatment of *Coli Bacilluria and Pyelitis*. 2.30 P.M., Dr. J. L. Livingstone: Asthma and Desensitisation. 3.15 P.M., Mr. W. Gilliatt: A Few Practical Points in Gynæcological Cases. 3.45 P.M., Mr. Cecil Wakeley and Mr. H. L. C. Wood: Injection Treatment of Varicose Veins. 5 P.M., Dr. Douglas Firth: Felton's Antipneumococcal Serum. 3 P.M., Mr. John Everidge: Electro-coagulation Treatment of Enlarged Prostate. (This course is free to medical practitioners.)

MIDDLESEX HOSPITAL POST-GRADUATE COURSE.

FRIDAY, Sept. 30th.—2 P.M., Mr. A. E. Webb-Johnson: Operations.

SATURDAY, Oct. 1st.—10.15 A.M., Discussion introduced by Mr. F. Roques: Drugs of Value in Obstetric Practice, including Anæsthetics. 11.30 A.M., Dr. Izod Bennett: Late Rickets and Chronic Diarrhœa. 2 P.M., Mr. R. Vaughan Hudson: Demonstration of Surgical Patients.

ST. MARY'S HOSPITAL POST-GRADUATE COURSE.

FRIDAY, Sept. 30th.—10.15 A.M., Mr. A. Dickson Wright: Phlebitis. 11 A.M., Mr. Aleck W. Bourne: Backache in Women. 12 A.M., Sir William Willcox: The Systemic Effects, Diagnosis, and Treatment of Chronic Affections of the Appendix and Gall-bladder. 2.15 P.M., Mr. Leslie Williams: Anæsthesia and *Analgesia* in Obstetrics. 3.15 P.M., Dr. T. C. Hunt: Some Recent Methods of [illegible]

SATURDAY, Oct. [illegible] [illegible]lley: Purulent Nasal D[illegible] Treatment, with lantern demonstrations. 11 A.M., Dr. Robert *Hutchison: Pink Disease.* 12 A.M., Dr. Reginald Miller: School Problems in Private Practice. 2.15 P.M., Dr. S. Vere Pearson: Modern Developments in Sanatorium Treatment. 3.15 P.M., Mr. T. G. Stevens: Causation and Treatment of Maternal Injuries in Childbirth.

SUNDAY.—1[illegible] Prostatic Proble[illegible], of *B. coli* [illegible] M., [illegible]nts Mr. V. [illegible] about Appendicitis. *(This course is free to medical practitioners.)*

WESTMINSTER HOSPITAL POST-GRADUATE COURSE.

FRIDAY, Sept. 30th.—10.30 A.M., Mr. Stanley Dodd: Extra-uterine Gestation. 11.30 A.M., Mr. C. D. Read: Post-Menopausal Hæmorrhage. 3 P.M., Dr.

De Souza: Ward Demonstration. 4.30 P.M., Mr. G. Mullally: Diseases of the Colon.

SATURDAY, Oct. 1st.—11 A.M., at Springfields Mental Hospital, Dr. R. Worth: Mental Cases. This course is open only to men graduates. It is organised by the Fellowship of Medicine and Post-Graduate Medical Association, 1, Wimpole-street, W.1, from whom further particulars can be obtained.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Sept. 26th, to SATURDAY, Oct. 1st.—WESTMINSTER HOSPITAL, S.W. Post-graduate course in General Medicine and Surgery. All day. Open to men graduates only. (See above.)—BETHLEM ROYAL HOSPITAL, Monks Orchard, Eden Park, Beckenham. Tues. and Frid., at 11 A.M., Demonstration in Psychological Medicine. (Open only to Members of the Fellowship.)

MANCHESTER ROYAL INFIRMARY.

TUESDAY, Sept. 27th.—4.15 P.M., Mr. H. H. Rayner: Treatment of Cancer of the Rectum.

FRIDAY.—4.15 P.M., Dr. P. B. Mumford: Demonstration of Dermatological Cases.

CENTRAL LONDON NOSE, THROAT, AND EAR HOSPITAL, Gray's Inn-road, W.C.

FRIDAY, Sept. 30th.—4 P.M., Mr. J. D. McLaggan: Tuberculosis of the Larynx.

Appointments

CHAPMAN, W. STANLEY, M.D. Lond., F.R.C.S. Eng., has been appointed R.M.O. Bolingbroke Hospital.

WILLIAMS, D. A. J., L.R.C.P. Lond., M.R.C.S., Certifying Surgeon under the Factory and Workshop Acts for the Tregaron District of the County of Cardigan.

Vacancies

For further information refer to the advertisement columns

Archway Hospital, Archway-road, Highgate, N.—Asst. M.O. £350.

Belgrave Hospital for Children, 1, Clapham-road, S.W.—Two H.P.'s and H.S. Each at rate of £100.

Bethnal Green Hospital, Cambridge-road, E.—Two Asst. M.O.'s. £350.

Brighton Sanatorium and Infectious Disease Hospital.—Jun. Res. M.O. At rate of £150.

Bromsgrove, Worcestershire Mental Hospital, Barnsley Hall.—Second Asst. M.O. £350.

Cancer Hospital, Fulham-road, S.W.—H.S. At rate of £100.

Canterbury, Kent and Canterbury Hospital.—H.S. At rate of £125.

Central London Ophthalmic Hospital, Judd-street, W.C.—Asst. Surgeon.

Chester, East Lancashire Tuberculosis Colony, Barrowmore Hall, Gt. Barrow.—Asst. M.O. At rate of £275.

Colchester, Severalls Mental Hospital.—Jun. Asst. M.O. £510.

Dublin, Mercer's Hospital.—Hon. Visiting Surg.; also Radiologist.

East London Hospital for Children, &c., Shadwell, E.—Asst. Surgeon to Nose, Throat, and Ear Dept. Res. H.P. £125. Also Asst. Physician. £40.

Glasgow Eye Infirmary.—Clin. Assts. Each £35.

Halifax Royal Infirmary.—Third H.S. At rate of £150.

Hertford County Hospital.—H.S. At rate of £200.

Hospital for Consumption and Diseases of the Chest, Brompton, S.W.—Asst. Res. M.O. At rate of £150. Three H.P.'s., H.S., and Jun. H.P. Each at rate of £50.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Res. M.O. and H.P. At rate of £150 and £100 respectively. Also Hon. Anæsthetist.

Hospital for Sick Children, Great Ormond-street, W.C.—H.P. and H.S. Each at rate of £100.

Hospital for Women, Soho-square, W.—Res. M.O. At rate of £100.

Hospital of St. John and St. Elizabeth, 60, Grove End-road, N.W.—Anæsthetist. £50.

Hove, Lady Chichester Hospital.—Jun. H.P. At rate of £50.

Ipswich, East Suffolk and Ipswich Hospital.—H.S. £120.

Lambeth Hospital, Brook-street, S.E.—Asst. M.O. £350.

Leamington Spa, Warneford General Hospital.—Res. H.S. and H.P. Each £165.

Liverpool, Alder Hey Children's Hospital, West Derby.—Sen. Asst. Res. M.O. £400.

Liverpool, St. Paul's Eye Hospital, Oldhall-street.—H.S. At rate of £145.

London Lock Hospital, 91, Dean-street, W.—Surg. Reg. £100.

Maidstone, Kent County Mental Hospital.—Asst. M.O. £509.

Manchester, [illegible] Pathologist. £200. Also H.S. A[illegible]

Manchester, [illegible] *l, Pendlebury.*—Res. M.O. At rate [illegible]

Metropolitan Hospital, Kingsland-road, E.—Sen. and Jun. H.P.'s and two Cas. O.'s. Each at rate of £100.

Mile End Hospital, Bancroft-road, E.—Asst. M.O. £350.

Miller General Hospital, Greenwich-road, S.E.—Hon. Surgeon to Nose, Throat, and Ear Dept.

Paddington Green Children's Hospital, W.—H.S. At rate of £150. Also Two Clin. Assts. to Special Depts.

Park (Fever) Hospital, Hither Green, S.E.—Res. Med. Supt. £1100.

Princess Beatrice Hospital, Richmond-road, Earl's Court, S.W. Res. M.O. At rate of £110.

Queen Charlotte's [illegible] *one-road, N.W.*—Res. M.O. for [illegible] smith, W. £200.

Queen's Hospital [illegible] *, E.*—Ophthalmic Surgeon.

Rhondda Urban District Council.—Temporary Asst. M.O. and Asst. School M.O. £500.

Royal Army Medical Corps.—25 Permanent Commissions.

Royal Eye Hospital, St. George's-circus, S.E.—Eighteen Clin. Assts. Pathologist, £100. Twelve Refractionists for L.C.C. Dept. Each £80. Also Nine Hospital Refractionists. Each £50.

Royal Free Hospital, Gray's Inn-road, W.C.—Res. Cas. O. At rate of £150.

Royal London Ophthalmic Hospital, City-road, E.C.—Two Out-patient Officers. Each £100.

Royal Society, Burlington House, W.—Lawrence Research Studentship. £200.

Royal Waterloo Hospital for Children and Women, Waterloo-road, S.E.—Hon. Clin. Asst.

St. Helens County Borough.—Asst. M.O.H. £600.

St. Leonard's Hospital, Hoxton-street, N.—H.P. At rate of £80.

St. Leonard's-on-Sea, Buchanan Hospital.—Sen. H.S. At rate of £175.

St. Mary Islington Hospital, Highgate Hill, N.—Asst. M.O. £250.

St. Pancras Hospital, Pancras-road, N.W.—Asst. M.O. £250.

South-Eastern Hospital for Children, Sydenham, S.E.—Jun. Res. M.O. At rate of £120.

Staff[illegible].—H.S. and H.P. At r[illegible]

Sutto[illegible] £150.

Weste[illegible] *rylebone-road, N.W.*—Hon. Asst. Surgeon.

West London Hosp[illegible] W.—Hon. Anæsthetist. Also [illegible]

Westminster Hospi[illegible] Asst. H.S. At rate of £52.

Wolverhampton Royal Hospital.—H.S. for Ear, Throat, and Nose Dept. At rate of £100.

The Chief Inspector of Factories announces vacant appointments for Certifying Factory Surgeons at Ulceby (Lincoln) and Guiseley (York).

Births, Marriages, and Deaths

BIRTHS

CURWEN.—On Sept. 17th, at Hove, the wife of Dr. E. Cecil Curwen, of a daughter.

HOBBS.—On Sept. 16th, at Old Court, Ealing, the wife of Dr. A. N. Hobbs, Woodville-road, Ealing, of a daughter.

MACRAE.—On Sept. 16th, at Colinton, Scotland, the wife of Alexander Murray MacRae, West African Medical Staff, of a daughter.

MCALEER.—On Sept. 10th, at Reay Bank, Helensburgh, the wife of Dr. T. B. McAleer (Nigeria), of a daughter.

PYPER.—On Sept. 11th, at Rhodes, North Berwick, the wife of Major J. C. Pyper, O.B.E., I.M.S., of a daughter.

STEEL.—On Sept. 13th, at a nursing home, the wife of Dr. W. Deane Steel, Henwick-road, Worcester, of a son.

MARRIAGES

TAYLOR—PEARSON.—On Sept. 17th, at the Church of St. Bartholomew-the-Great, Hermon Taylor, M.Ch., F.R.C.S., to Méarie Amélie, second daughter of Mr. and Mrs. A. M. Pearson, of Stamford-hill, N.

DEATHS

FREEMAN.—On Sept. 15th, at Angel Corner, Bury St. Edmunds, Colonel Ernest Carrick Freeman, C.M.G., late R.A.M.C., aged 72.

HODGSON.—On Sept. 13th, at Chalgrave, Exmouth, J. Willoughby Hodgson, O.B.E., M.D., aged 75.

MACGILLIVRAY.—On Sept. 17th, at Glencairn-crescent, Edinburgh, Charles Watson Macgillivray, M.D., F.R.C.S. Edin., aged 81.

ROSS.—On Sept. 16th, at the Ross Institute, Putney Heath, S.W., Colonel Sir Ronald Ross, K.C.B., K.C.M.G., F.R.S., Nobel Laureate, I.M.S. (retired), aged 75.

SIMSON.—On Sept. 13th, suddenly, Sir Henry John Forbes Simson, K.C.V.O., M.B., C.M., F.R.C.S. Edin., F.R.C.P. Lond., F.C.O.G., of Grosvenor-square, W., aged 59.

SYMONDS.—On Sept. 14th, at Rowney, Mount Park, Harrow-on-the-Hill, Sir Charters James Symonds, K.B.E., C.B., M.S., F.R.C.S., LL.D., Consulting Surgeon to Guy's Hospital, aged 80.

WAJID.—On Sept. 12th, Mohammed Abdul Wajid, M.D., F.R.C.S.E., M.A., B.Sc., Ch.B., D.P.H., F.R.F.P.S.G., of Harley-street, aged 46.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

HARROGATE NEW GENERAL HOSPITAL.—On Saturday last the Princess Royal opened this institution, which has cost £110,000. The administration block is in the centre of the building, and the two-storeyed wings have accommodation for 114 patients. The out-patients' department is entirely self-contained. The 50 nurses are housed in a building of three floors.

Tinto Mines, where malaria was then endemic. Laveran had found "bodies" in the red blood corpuscles, and the mosquito had been suggested as a "carrier." Macdonald had worked under Laveran, and, two months before Ross's great discovery, he had sent mosquitoes, fed on malarial blood, from Rio Tinto to Paris—but they died en route. On leaving Rio he joined his uncle, the late W. A. Mackay, at the British Clinic, Huelva, Spain, where he developed abdominal surgery to such effect that one of the main streets in that town is now named "Calle Macdonald." His contributions to surgical literature are to be found in the medical journals of England, Spain, and France; one of these recorded the results of 205 cases of gastro-enterostomy, another dealt with the prevalence of chronic gastric disease in Spain.

Of the man himself, Dr. Halliday Sutherland, his cousin, writes: "Seriousness was the main trait of his character. Everything he did, in work or recreation, he tried to do well. He was a first-rate angler and a fair shot. In tennis, golf, and cricket he studied the technique of the game. During holidays he watched the technique of other surgeons in France, England, and America. As he once remarked, 'They don't put everything in their books and articles.' He was modest, and with strangers had a grave and formal manner, but with intimate friends he showed a keen appreciation of humour. Over his cases he took great care in diagnosis and treatment; he was neither a bold nor a cautious surgeon, but operated with assurance, skill, and an eye which never overlooked the smallest detail in technique. His average time for a posterior gastro-enterostomy was *20* minutes, but he never hurried. He never wrote about a case until he had first read the literature. In conversation he was a good listener, but his critical faculty was always alert, and he had a keen appreciation of French, Spanish, and English prose. His stability and strength of character was best known to his relatives, who in times of sickness relied implicitly on his judgment."

In 1916 Dr. Macdonald married Elizabeth, second daughter of the late Peter Henderson, of Huntly, Aberdeenshire, who survives him.

J. Adie: Neurological Lesions of Sudden Onset. 3 P.M., Dr. E. C. Warner: The Differential Diagnosis of the Principal Causes of Jaundice. 4 P.M., Dr. K. Shirley Smith: The Treatment of Heart Failure. (This course is open only to graduates and students of the *school.*)

KING'S COLLEGE HOSPITAL POST-GRADUATE COURSE.

SATURDAY, Oct. 1st.—2 P.M., Mr. Yates Bell: The Treatment of Coli Bacilluria and Pyelitis. 2.30 P.M., Dr. J. L. Livingstone: Asthma and Desensitisation. 3.15 P.M., Mr. W. Gilliatt: A Few Practical Points in Gynæcological Cases. 3.45 P.M., Mr. Cecil Wakeley and Mr. H. L. C. Wood: Injection Treatment of Varicose Veins. 5 P.M., Dr. Douglas Firth: Felton's [illegible] P.M., Mr. John Everidge: [illegible] of Enlarged Prostate. [illegible] practitioners.)

MIDDLESEX HOSPITAL POST-GRADUATE COURSE.

FRIDAY, Sept. 30th.—2 P.M., Mr. A. E. Webb-Johnson: Operations.

SATURDAY, Oct. 1st.—10.15 A.M., Discussion introduced by Mr. F. Roques: Drugs of Value in Obstetric Practice, includ[illegible], Dr. Izod Bennett: Late [illegible]hœa. 2 P.M., Mr. R. Vaugh[illegible] of Surgical Patients.

ST. MARY'S HOSPITAL POST-GRADUATE COURSE.

FRIDAY, Sept. 30th.—10.15 A.M., Mr. A. Dickson Wright: Phlebitis. 11 A.M., Mr. Aleck W. Bourne: Backache in Women. 12 A.M., Sir William Willcox: The Systemic Effects, Diagnosis, and Treatment of Chronic Affections of the Appendix and Gall-bladder. 2.15 P.M., Mr. Leslie Williams: Anæsthesia and Analgesia in Obstetrics. 3.15 P.M., Dr. T. C. Hunt: Some Recent Methods of Treatment.

SATURDAY, Oct. 1st.—10.15 A.M., Mr. Herbert Tilley: Purulent Nasal Discharges: their Diagnosis and Treatment, with lan[illegible] A.M., Dr. Robert Hutchiso[illegible].M., Dr. Reginald Miller: S[illegible] Practice. 2.15 P.M., Dr. S. Vere Pearson: Modern Developments in Sanatorium Treatment. 3.15 P.M., Mr. T. G. Stevens: Causation and Treatment of Maternal Injuries in Childbirth.

SUNDAY.—[illegible] Jones: Prostatic Proble[illegible]: Treatment of *B. col*[illegible] Diet. 12 A.M., Mr. V[illegible]oversial Points about Appendicitis. (This course is free to medical practitioners.)

WESTMINSTER HOSPITAL POST-GRADUATE COURSE.

FRIDAY, Sept. 30th.—10.30 A.M., Mr. Stanley Dodd: Extra-uterine Gestation. 11.30 A.M., Mr. C. D. Read: Post-Menopausal Hæmorrhage. 3 P.M., Dr.

One other subject is receiving much attention—namely, the "freshness" of waters and the desirability of taking them at the source. It has not yet been definitely determined what constitutes "freshness" in all cases, but in some radio-activity, colloidal properties, and electrical conditions explain certain of the phenomena observed.

REDUCTION OF TUBERCULOSIS MORTALITY IN A HUNGARIAN TOWN

IN 1925 the town of Pesterzsébet stood thirty-sixth in the list of 52 towns in Hungary as regards the mortality from tuberculosis. In 1931 the town stood first. The fact deserves record, as Dr. Eugen Szalai, the medical superintendent of the municipal lung clinic, attributes this remarkable progress to the systematic use of a vaccine. In a recent article[1] Dr. Szalai sets out some details of the course of the reduction of the mortality from tuberculosis in the town, and in meeting sundry criticisms builds up a strong case for attributing it to the prophylactic and therapeutic use of Friedmann's vaccine. In 1925 the mortality from tuberculosis in Pesterzsébet was 2·9 per 1000, and in 1931 it was 1·1, while in Pest, the commercial and industrial part of Budapest, the rate was 2·9 per 1000 in 1925 and 2·3 in 1931. A criticism made of the figures has been that deaths of inhabitants of Pesterzsébet occurring in other towns have been omitted, and Dr. Szalai set himself the gigantic task of tracking down the actual dwelling-places of all patients dying from tuberculosis in his city and in Pest and its suburbs. He shows that on this basis citizens of Pesterzsébet, wherever they died of tuberculosis, showed a mortality-rate from this disease of 4·15 per 1000 in 1925, and only 2·3 in 1931, while similar figures for Pest show only a small decrease from 2·36 in 1925 to 1·96 in 1931. The next point he makes is in answer to the criticism that his results are due to general hygienic measures. He emphasises that Pesterzsébet is a relatively unhygienic town. Only 10 per cent. of those dying from tuberculosis there had more than one room for the whole family, and only 1 per cent. of the fatal cases had a room of their own. In contrast to this he takes the town of Kleinpest, a neighbour municipality of Pest, and adjacent to Pesterzsébet. Kleinpest has a large garden suburb, where at least a third of the population live in excellent surroundings, with houses of two to three rooms. The inhabitants are mostly employees of the postal and railway services and in receipt of a steady income. Thanks to these hygienic surroundings the mortality from tuberculosis in Kleinpest has slowly decreased from 1·9 per 1000 in 1925 to 1·55 in 1931, but actually the decrease in the town where Friedmann's vaccine is used amid bad social and hygienic conditions is still greater, and the rate in 1931 is lower. A further point made by Dr. Szalai concerns the mortality from tuberculous meningitis. In 1931 eight children died from this complaint in Pesterzsébet, none of them having received the vaccine; while of 1723 children who were vaccinated with this material, either because they were suspected of having tuberculosis or because they were forced to live in the same house as a case of open tuberculosis, not a single one has become seriously affected. Dr. Szalai found that two towns in Hungary besides Pesterzsébet had shown some though less remarkable improvement in mortality from tuberculosis. In one of these he discovered that a large number of the "inhabitants" were actually inmates of a large jail where, thanks to hygienic measures, a great decrease in tuberculosis had recently been effected; while in the other place Friedmann's vaccine was also being used, although not so systematically as in Pesterzsébet. Dr. Szalai's investigations certainly merit attention. Details of his methods have been given in a previous paper[2]; he emphasises here the relative cheapness of the scheme and the complete harmlessness of the vaccine. He claims that if every early case of tuberculosis and every suspected case were inoculated, especially in childhood, tuberculosis would be irradicated completely in a comparatively short time.

STAGECRAFT FOR HOSPITAL ENTERTAINMENTS

THE Christmas entertainments in hospitals, preparation for which may begin almost with the autumn session, are as a rule very successful. This may be due to the goodwill of the audience in wards or out-patient departments, as well as to the intrinsic merits of the performance. Generally the individual artists are prepared to take great trouble in rehearsal, and if the turns lack polish, it is because the producer lacks technical equipment and knowledge. To meet his present needs a course of dramatic production will be held on alternate Sundays during the autumn at the Everyman Theatre, Hampstead, London, N.W. 3, beginning at 3 P.M. on Sunday, Oct. 9th. The course will include every branch of play production and stage technique, and programmes for staff and ward concerts of a simple, light, and effective nature will be rehearsed. The work of erecting temporary stages and devising settings will be demonstrated. The course is organised by the Little Theatre, Citizen House, Bath. The opening demonstration will be free to all interested.

CHRONIC ARTHRITIS OF THE HIP

THE work of the late Dr. Louis Duvernay on chronic osteo-arthritis of the hip has provided his son Dr. J. Graber-Duvernay with the basis for a memoir of 170 pages dealing with all phases of the treatment of this condition.[3] The first two sections are devoted to a discussion of accepted principles of medical and surgical treatment. The use of drugs, the elimination of septic foci, vaccine therapy, general principles of hygiene, physiotherapy and hydrotherapy are considered in the medical section, and the indications for trochanteric osteotomy, bifurcation osteotomy, arthrodesis, and arthroplasty are dealt with in the surgical section. The third section is the only part of the paper which has any claim to originality. A palliative operation is described which may be performed under local anæsthesia and is therefore applicable in patients too old and too fragile to withstand the shock of a major operation. Apart from certain minor modifications, the operative procedure is that which was described in 1919 by Robertson-Lavalle for the treatment of tuberculous joints. A small incision is made over the base of the great trochanter, the neck of the femur is drilled, and a long thin bone graft driven through the drill hole. Robertson-Lavalle advocated the use of an autogenous bone graft, but in osteo-arthritic joints Duvernay has found that a boiled beef bone graft 5 mm. wide and 6 cm. long is equally effective. In three cases the femoral neck was drilled and no bone graft used. It is claimed that by this operation a local hyperæmia is induced which relieves the pain, increases the range of movement, and augments the palliative effect of external thermal applications. The author attempts to provide a sound pathological basis for the operation by quoting the work of Leriche and Policard who have shown that sclerosis of bone is the result of impairment of its blood-supply. On these grounds, it is argued that the drilling of the neck of the femur will give rise to hyperæmia which will reduce the degree of sclerosis of the femoral head and therefore relieve the pain. It is unfortunate that no radiographic

NOTES, COMMENTS, AND ABSTRACTS

THE NEW CLASSIFICATION OF WATERS

BY S. JUDD LEWIS, D.SC., F.I.C., PH.C.

UNTIL the early part of last year there was perhaps no part of the study of natural medicinal waters more disappointing than their classification. Literally scores of systems of classification had been suggested; some depending on their chemical properties, some on their concentration, some on their electro-conductivity, some on their principal medicinal properties, but none appears to have satisfied any wide class of readers nor to have given complete satisfaction to the originators.

Happily a committee, appointed by the International Society of Medical Hydrology, has now been able to propose a new classification which seems to have found universal favour. It is significant that those who had fostered systems of classification of their own have expressed their unqualified approval, and no one has levelled any serious criticism of it, either as a whole or in its details. One may assume, therefore, that this exceptionally thorny question has been settled.

The Scheme

The classification is threefold: chemical, physical, and medicinal. A formula by which the prescribed classification is expressed has been devised. Thus, in the *chemical* classification the composition is given in terms of one or more of its dominant or most active elements—for example, chloride, calcium, iron, or arsenic—while elements which are subsidiary chemically, but of medicinal interest, may be added in brackets. The concentration is given in terms of milli-normality (N/1000)—an expression familiar to all in chemistry—and the number or numbers so derived show at a glance the "strength" of the water. The "reaction," which in many cases is more or less alkaline, is given precisely in terms of the pH value of the water. In this way all that the physician needs to know regarding the classification of the chemical properties of the water is seen at a glance. It constitutes an epitome of the whole analysis. The gaseous properties of the water are also presented.

Provision is made for exhibiting the *physical* properties of the water, chief among these are the temperature of the water at the source, its tonicity, radio-activity, and occasionally its colloidal properties.

The *medicinal* classification should be based on analytical data and clinical experience, and be expressed in not more than ten words, using well-recognised descriptive terms, such as (for their internal action) aperient, diuretic, solvent, alterative, tonic; and (for their external action) temperature effects, sedative, stimulant, counter-irritant. Disorders for which the water is particularly indicated should then be named—for example, dyspepsia, rheumatism, neurasthenia, eczema. When desired this classification may be followed by directing the reader to reports in which the medicinal properties of the water are more fully discussed. The limitation to ten words may appear restrictive at first sight, but actually they are more than are used commonly as the headings of a classification.

The main idea is to present to the physician a bird's-eye view of the essential properties of a water from every angle.

An Example

How well this new classification works may be judged from the two following published examples taken from the International Register of Spas and Medicinal Waters.

WATER NO. 1

Chemical.—Composition: chloride, calcium (Br). Ionic concentration: N/1000. Total = 320; Na, 87; Ca, 71; Cl, 153; Br, 0·7; I, 0·006. Reaction: Normal; pH = 7·6.

Physical.—Cold, 10° (51° F.), hypertonic.

Medicinal.—Aperient alterative; surface action stimulant; inhalation; rheumatism, chronic catarrh; children. (See also *Medical Review*, 1912, vii., 45.)

WATER NO. 2

Chemical.—Composition: calcium, bicarbonate. Ionic concentration: N/1000. Total = 11·0; Ca, 2·9; Mg, 1·6; Mn, 0·004; Cl, 1·1; HCO_3, 4·2. Reaction: alkaline; pH = 9·2. Gaseous, nitrogen.

Physical.—Thermal, 22° (72° F.). Radio-active.

Medicinal.—Diuretic, solvent; surface action sub-thermal, sedative; fibrositis, gout, renal insufficiency.

Expressing the concentration in terms of milli-normality *enables one to make comparisons* of waters in every direction; thus in these examples Ca : Ca = 71 : 2·9 (i.e., 24 to 1); Cl : Cl = 153 : 1·1 (140 to 1); Cl : Ca = 153 : 71 (2 to 1); Ca : total = 71 : 320 (nearly 1 to 4) in No. 1, or 2·9 : 11 (1 to 4) in No. 2 also; but Cl : total = 153 : 320 (1 to 2) in No. 1, or 1·1 : 11 (1 to 10) in No. 2. It is easy to visualise the desired ratio at a glance.

Advantages

It is very desirable that this classification should be followed in this country as closely as possible. It serves the prime purpose of classification—namely, to enable comparison of one water with another. It is perhaps unique in making provision for presentation of valuable elements occurring in only very small quantity which have received far too little attention in the past. This is exemplified with two elements in the foregoing examples—namely, iodine in the first, 0·006, and manganese in the second, 0·004. When it is considered that iodine in so small a quantity as 46 parts per 1000 millions of London water determines the health of the community in certain aspects, especially in avoiding goitre, and that manganese in similar proportion will influence the productivity of many plants, these small quantities cannot possibly be passed by as of no significance.

It is desirable that increased attention should be paid to the international direction that "the medicinal classification should be based on analytical data" as well as on clinical experience. The science and practice of analytical chemistry have made such strides during the last few years that analyses made a generation ago cannot be considered adequate to modern requirements of medicine. Numerous published analyses of springs give nothing beyond data relating to those elements present in largest proportion, those elements occurring in small quantity being wholly neglected. Difficulties experienced formerly in their discovery have been entirely removed since the introduction of the modern quartz spectrograph and recent methods of micro-analysis. Prof. M. Loeper[1] believes that the rôle of boron in waters is important, and shows that it is found in 11 out o 12 French waters examined. I found boron by means of the spectrograph in the majority of British waters of various kind, and raised the same question 18 years ago.[2] One may also learn, from the work of W. Brenchley and others, that "the function of boron" (1 in 12,500,000 to 1 in 25,000) "in the case of the broad bean appears to be probably nutritive rather than catalytic, since a supply is required throughout the life of the plant. A parallel is drawn between the action of boron on plants and the vitamins on animal life" (Lewis[3]).

The new classification exhibits all important information common to the vast majority of natura waters, and hence it is as much as can be done on an international basis; but it also gives space for addin details of special character—for example, for describing the biological activities of a water; its colloida properties; its liability to change or otherwise by bottling; and other features of local interest.

ADDRESSES AND ORIGINAL ARTICLES

LOCAL OUTBREAK OF DEVONSHIRE COLIC

BY M. C. N. JACKSON, M.B. LOND.

AND

L. N. JACKSON, *M.C.*, D.M. OXF.

ALTHOUGH Devonshire colic was probably an ndemic disease long before that time, its cause was ot determined until the latter part of the eighteenth ntury. G. Musgrave,[1] in 1703, stated that the colic hich occurred in Devonshire and which was somemes associated with paralysis was due to the ccessive consumption of crude cider which was too id. J. Huxham,[2] who in 1752 graphically described e colicky pains and paralysis, took the view that e disease was caused by the tartar extracted from e apples in the process of cider brewing. It was ot until 1767 that Sir George Baker, an alertinded Devonian, finally recognised that lead colic nd Devonshire colic were one and the same disease. e demonstrated[3] that Devonshire cider contained ad, whereas Herefordshire cider did not, and rther drew attention to the fact that in Devonshire he cider presses and storage tanks were very comonly lead-lined. His exposure of this practice, and hat of "correcting" sour cider by the addition of etallic lead, litharge, or lead acetate, produced a torm of criticism, and he was denounced as a traitor o his county.

Lead has long ceased to play any part in the nanufacture or storage of cider, nevertheless minor outbreaks of plumbism among cider-drinkers occur rom time to time. The following is an account of such an outbreak recently noted among habitual cider-drinkers in a country district near Exeter. When the connexion between plumbism and cider-drinking first became evident to us, the public-houses frequented by our patients were investigated. It was found that certain of the publicans were in the habit of drawing their cider from the cask to the engine through lead pipes. Subsequent analysis of samples of cider (*a*) from cask and (*b*) from engine proved that lead contamination occurred in the conducting pipes and not, as in Baker's cases, during the process of manufacture or storage. In passing, it is interesting to note the relative insusceptibility of most persons to this form of lead poisoning as indicated by the comparatively few cases that have come to us complaining of symptoms, despite the fact that much of the cider drunk in this district must have been thus contaminated for many years.

Clinical Notes

All our cases occurred in males. Other sources of lead intake were, as far as possible, excluded. The cases fall into two groups: 1. Those complaining of symptoms referable to lead poisoning. 2. Symptomless cases investigated because they were known to be habitual cider-drinkers frequenting the same public-houses as those in group 1.

The clinical examinations of these cases were made in the autumn of 1931.

1. CASES WITH SYMPTOMS

CASE 1.—A. B., aged 59, an army pensioner, has had repeated attacks of intestinal colic and constipation since 1922. In 1926 pallor and loss of power in both forearms were noted. In 1928 a stippled blue line appeared on the gums. The weakness and wasting of forearms and hands have increased since then. He had malaria and typhoid in 1898 and acute urethritis in 1900, followed by urethral strictures and several attacks of gonococcal arthritis. There is no history of headaches or fits. He has been a cider-drinker for 20 years, and admits to a maximum of five pints daily. Since the war he has been obtaining his cider from houses A, B, and C. He was a large pale man with bilateral wrist-drop, and a stippled blue line on the gums round his few remaining teeth. Blood pressure 165/100. There were no other relevant physical signs.

Laboratory findings.—Blood: red cells 3,300,000 per c.mm., hæmoglobin 48 per cent., punctate basophilia present. Urine: albumin and pus present, lead present. Wassermann reaction negative.

CASE 2.—C. D., aged 60, a foreman labourer employed by the district council. Complained of attacks of giddiness in 1923, and nystagmus was noted at that time. This symptom and sign were again noted in 1928. In November, 1929, he began to have attacks of severe intestinal colic with vomiting and constipation. At this time weakness of wrists was complained of and a blue line noted. In February, 1930, when pulling on a rope, he noticed sudden marked increase of weakness in his hands and wrists. He also noticed for the first time some weakness of his legs. There is no history of headaches or fits. Although he only admits to a maximum of three pints daily he is known to have been a heavy cider-drinker for at least ten years, and to have frequented all the public-houses in the town during this time. His friends state that he has often obtained a free drink by offering to consume the first glass of cider drawn from the engine in the morning. In June, 1930, he was admitted to the Royal Devon and Exeter Hospital under the care of Dr. Charles Seward, where he was found to have diabetes mellitus. There was wasting of both hands, especially the thenar muscles, and loss of power in the extensors of both wrists. Albuminuria and punctate basophilia were found. In July, 1931, he was admitted to the London Hospital under the care of Dr. Donald Hunter. The diagnosis of diabetes mellitus was confirmed. Blood pressure 135/85. There was gross wasting of both forearms, weakness and wasting of extensors of wrists and small muscles of hands, and of both legs below the knees, especially of dorsi-flexors. There was also analgesia to pinprick, heat, and cold over the segmental areas C.4 to D.2 on both sides.

Laboratory findings.—Blood: red cells 4,000,000 per c.mm., hæmoglobin 64 per cent., punctate basophilia present. Urine: sugar and albumin present, lead not found. Wassermann reaction negative. Fæces: lead present.

In the opinion of Dr. Donald Hunter and Dr. George Riddoch the paralysis of the upper limbs and the areas of analgesia were due to a hæmatomyelia incurred at the time of the accident while felling trees. The foot-drop was evidently due to lead palsy, and it improved following two long courses of ammonium chloride, together with a low calcium diet.

CASE 3.—E. F., aged 50, a general labourer, was referred for dental treatment in 1928, at which time a stippled blue line on the gums was noted. In September, 1929, he complained of morning retching, central abdominal pain, and loss of weight. In January, 1930, he complained of abdominal pain and constipation, and was pale, wasted, and tremulous. In April, 1931, he had a return of abdominal symptoms, and was admitted to the Royal Devon and Exeter Hospital under the care of Dr. C. J. Fuller. He had typhoid in 1915, but had always been otherwise healthy. There is no history of headaches or fits. He began to drink cider in 1921, having previously been a beer-drinker. He admits to an average consumption of five pints daily, rising occasionally to ten pints daily. He obtains his cider from houses A, B, D, E, F, and G. He has, acting on advice, given up cider since his discharge from hospital, and has much improved. He was a healthy-looking, edentulous man, with a dull mentality. Blood pressure 140/95. There was slight wasting of the small muscles of both hands but no noticeable weakness and a fine tremor of the tongue and hands.

Laboratory findings.—Blood: punctate basophilia present. Urine: lead present, no albumin found.

[3] Med. Trans. Lond., 1772, i., 175.

evidence is brought forward to support the theory. Moreover, it is curious that in the first case recorded, the drill hole and graft were badly placed and instead of lying in the femoral neck, the graft is situated horizontally in the upper shaft of the femur at the level of the small trochanter; and yet it is claimed that there was complete restoration of joint movement, relief of pain, and a 90 per cent. improvement in the condition of the joint, which had been maintained when the patient was re-examined 12 months later. Ten cases are described in detail and all of the results are said to be satisfactory. In none of the cases has a sufficient period of observation been maintained to convince the reader that the improvement will be lasting. It is difficult to believe that simple drilling of the neck of the femur can permanently alter the vascular relationships of the bone, and since we know that transplanted beef bone is fairly rapidly absorbed, and the host bone restored to its original condition, it is not easy to see how drilling and grafting can give rise to more than a temporary alleviation of symptoms, even if it be accepted that the hyperæmia so induced does in fact give rise to the degree of improvement which is claimed.

A QUESTION OF ASSESSMENT

A PRACTITIONER asks whether he is entitled to deduct from his income-tax return some very heavy medical fees paid with the object of being kept fit for work—which would otherwise have been impossible. The point, we are informed, is dealt with quite definitely in the Income Tax Acts. Among the rules governing Schedule "D" is to be found one which states that no sum shall be deducted in respect of any disbursements or expenses of maintenance of the parties, or of any sums expended for private purposes distinct from the purposes of the vocation. The passage is somewhat involved and may be misread, but in practice it definitely excludes medical treatment of the tax-payer, although on common-sense grounds the retention or regaining of a healthy bodily condition might well be regarded as essential for professional work.

NATURAL RADIUM WATER

"A. B.," having read the article entitled Radium as a Pharmaceutical Poison, by Dr. H. A. Colwell and Prof. Sidney Russ, in THE LANCET of July 23rd (p. 221), writes to ask whether the continued internal use of natural radium waters, or of water containing thorium, is devoid of risk, especially the risk of provoking cancer. We are assured that there is no evidence to show that any body of people have been harmed by drinking pure natural waters which contain radium and thorium. The references in the article mentioned were to the occurrence of sarcoma following the drinking of water in which the natural radio-active content had been artificially raised. Presumably if it had been raised with thorium to the same radio-active degree as with radium the results would have been similar, but there seems no reason for apprehension where a natural product is in question.

EARLY SIGNS OF MAJOR MENTAL DISORDERS

AT a meeting of the Paddington Medical Society, held on Sept. 13th, Dr. Frederick Dillon spoke of Early Signs of Major Mental Disorders from the point of view of the practitioner. He said that such early symptoms as depression, excitement, and insomnia were apt to be overlooked owing to their protean character and the circumstances under which general practice had to be carried on. They were, however, of great significance, and at a time when a patient was still engaged in a struggle to preserve his normal reactions, were liable to be productive of serious consequences. Early depression at a stage when the psychomotor functions were still active might easily end in suicide. The early stages of excitement might lead an individual into antisocial or other misdeeds of serious consequence. Insomnia was never a pathological condition in itself: it was the signal of a more far-reaching state of mind. Dr. Dillon compared the relative value of hypnotic drugs in the early psychoses, and expressed the opinion that the danger of habit formation might easily be exaggerated. In the discussion which followed, Sir John Collie deplored the tendency to overstress the medico-legal difficulties of certification. The "stigma" involved in certification might sometimes be best overcome by ignoring it. In any case early treatment might demand certification, and practitioners should not shirk their responsibilities in this respect.

A WARNING

WE are asked by the Chief Constable of South Shields to draw attention to a man who represents himself as "Dr. John Alexander Tolmie." This man is said to be identical with Andrew John Gibson, who has a number of convictions for obtaining money by fraud, &c., in New South Wales, at San Quentin (California), San Francisco, Durban, and Johannesburg, and at the Hants Assizes (from Bournemouth). In South Shields he got into conversation with a local practitioner, and was introduced by the latter to his bank manager, to whom he presented a bogus deposit certificate demand note for $10,000, drawn on the Provincial Treasurer's Office, Edmonton, Canada, and was given a cheque book containing 30 cheques, Nos. H/2 A. 17731 to 17760 (inclusive). He cashed a number of cheques and is now wanted on warrant. He also entered into an agreement for partnership with the local doctor.

"Dr. Tolmie," is described as: aged 52 years, height 5ft. 7½ in., complexion fresh, hair grey, eyes grey, small cyst on right side of face, indistinct dot on right forearm. It is desired that should he visit any practitioner information be immediately given to the local police.

INTERMITTENT HEADACHE IN WOMEN.—We are asked to state that the œstrogenic hormone isolated from the placenta and physiologically standardised by Prof. J. B. Collip at McGill, under the name emmenin, may be obtained directly in this country from the Glaxo Laboratories, 56, Osnaburgh-street, London, N.W.1.

ESSEX COUNTY HOSPITAL, COLCHESTER.—The Bishop of Chelmsford last week dedicated the chapel in the new nurses' home, which has been erected in memory of the late Mrs. Leeston Smith.

YORKSHIRE CRIPPLE CHILDREN'S HOME.—This home, which is situated at Kirby Moorside, has established a factory for the manufacture of the surgical appliances needed by the patients.

PLYMOUTH PAYING PATIENTS AND INSURANCE SCHEME.—A scheme with this title, sponsored by Plymouth Voluntary Hospitals Committee, will come into operation on Nov. 1st. It owes its inception to the desire of many persons who are debarred by the income limit from participation in the local penny-in-the-pound scheme. The plan is intended to assist people to pay the costs of their medical and surgical attention in any medical institution "if accepted at any such institution, whether in the general or private wards of a voluntary hospital or in a nursing home." The nursing home or hospital used must be fully recognised by the committee, and certain illnesses will be excluded. There is no income limit, residence in the Plymouth area is not a necessary qualification, and any recognised institution in the United Kingdom can be used. The annual subscription is a guinea a year, and the benefits are as follows: (*a*) £6 a week up to a maximum of four weeks towards costs allowed for an operation or serious illness in a voluntary hospital; (*b*) not exceeding £6 a week up to a maximum of four weeks towards costs allowed in a nursing home for an operation; (*c*) grant towards cost of maintenance as approved by the committee up to £6 per week for four weeks for a serious illness other than an operation in a nursing home. The maximum benefit in any one year is: Group A, single person, £26; group B, family of two, £60; group C, for each additional member over two in family, add £12. General practitioners' fees are not included.

ADDRESSES AND ORIGINAL ARTICLES

LOCAL OUTBREAK OF DEVONSHIRE COLIC

BY M. C. N. JACKSON, M.B. LOND.

AND

L. N. JACKSON, *M.C.*, D.M. OXF.

ALTHOUGH Devonshire colic was probably an
lemic disease long before that time, its cause was
t determined until the latter part of the eighteenth
tury. G. Musgrave,[1] in 1703, stated that the colic
ich occurred in Devonshire and which was some-
es associated with paralysis was due to the
cessive consumption of crude cider which was too
id. J. Huxham,[2] who in 1752 graphically described
e colicky pains and paralysis, took the view that
e disease was caused by the tartar extracted from
e apples in the process of cider brewing. It was
t until 1767 that Sir George Baker, an alert-
inded Devonian, finally recognised that lead colic
d Devonshire colic were one and the same disease.
e demonstrated[3] that Devonshire cider contained
ad, whereas Herefordshire cider did not, and
rther drew attention to the fact that in Devonshire
e cider presses and storage tanks were very com-
only lead-lined. His exposure of this practice, and
at of "correcting" sour cider by the addition of
etallic lead, litharge, or lead acetate, produced a
orm of criticism, and he was denounced as a traitor
his county.

Lead has long ceased to play any part in the
anufacture or storage of cider, nevertheless minor
utbreaks of plumbism among cider-drinkers occur
om time to time. The following is an account of
uch an outbreak recently noted among habitual
ider-drinkers in a country district near Exeter.
Vhen the connexion between plumbism and cider-
rinking first became evident to us, the public-
ouses frequented by our patients were investigated.
t was found that certain of the publicans were in
he habit of drawing their cider from the cask to the
ngine through lead pipes. Subsequent analysis of
amples of cider (*a*) from cask and (*b*) from engine
roved that lead contamination occurred in the con-
lucting pipes and not, as in Baker's cases, during
he process of manufacture or storage. In passing,
t is interesting to note the relative insusceptibility
f most persons to this form of lead poisoning as
ndicated by the comparatively few cases that have
ome to us complaining of symptoms, despite the
fact that much of the cider drunk in this district
must have been thus contaminated for many years.

Clinical Notes

All our cases occurred in males. Other sources of lead intake were, as far as possible, excluded. The cases fall into two groups: 1. Those complaining of symptoms referable to lead poisoning. 2. Symptomless cases investigated because they were known to be habitual cider-drinkers frequenting the same public-houses as those in group 1.

The clinical examinations of these cases were made in the autumn of 1931.

1. CASES WITH SYMPTOMS

CASE 1.—A. B., aged 59, an army pensioner, has had repeated attacks of intestinal colic and constipation since 1922. In 1926 pallor and loss of power in both forearms were noted. In 1928 a stippled blue line appeared on the gums. The weakness and wasting of forearms and hands have increased since then. He had malaria and typhoid in 1898 and acute urethritis in 1900, followed by urethral strictures and several attacks of gonococcal arthritis. There is no history of headaches or fits. He has been a cider-drinker for 20 years, and admits to a maximum of five pints daily. Since the war he has been obtaining his cider from houses A, B, and C. He was a large pale man with bilateral wrist-drop, and a stippled blue line on the gums round his few remaining teeth. Blood pressure 165/100. There were no other relevant physical signs.

Laboratory findings.—Blood: red cells 3,300,000 per c.mm., hæmoglobin 48 per cent., punctate basophilia present. Urine: albumin and pus present, lead present. Wassermann reaction negative.

CASE 2.—C. D., aged 60, a foreman labourer employed by the district council. Complained of attacks of giddiness in 1923, and nystagmus was noted at that time. This symptom and sign were again noted in 1928. In November, 1929, he began to have attacks of severe intestinal colic with vomiting and constipation. At this time weakness of wrists was complained of and a blue line noted. In February, 1930, when pulling on a rope, he noticed sudden marked increase of weakness in his hands and wrists. He also noticed for the first time some weakness of his legs. There is no history of headaches or fits. Although he only admits to a maximum of three pints daily he is known to have been a heavy cider-drinker for at least ten years, and to have frequented all the public-houses in the town during this time. His friends state that he has often obtained a free drink by offering to consume the first glass of cider drawn from the engine in the morning. In June, 1930, he was admitted to the Royal Devon and Exeter Hospital under the care of Dr. Charles Seward, where he was found to have diabetes mellitus. There was wasting of both hands, especially the thenar muscles, and loss of power in the extensors of both wrists. Albuminuria and punctate basophilia were found. In July, 1931, he was admitted to the London Hospital under the care of Dr. Donald Hunter. The diagnosis of diabetes mellitus was confirmed. Blood pressure 135/85. There was gross wasting of both forearms, weakness and wasting of extensors of wrists and small muscles of hands, and of both legs below the knees, especially of dorsi-flexors. There was also analgesia to pinprick, heat, and cold over the segmental areas C.4 to D.2 on both sides.

Laboratory findings.—Blood: red cells 4,000,000 per c.mm., hæmoglobin 64 per cent., punctate basophilia present. Urine: sugar and albumin present, lead not found. Wassermann reaction negative. Fæces: lead present.

In the opinion of Dr. Donald Hunter and Dr. George Riddoch the paralysis of the upper limbs and the areas of analgesia were due to a hæmatomyelia incurred at the time of the accident while felling trees. The foot-drop was evidently due to lead palsy, and it improved following two long courses of ammonium chloride, together with a low calcium diet.

CASE 3.—E. F., aged 50, a general labourer, was referred for dental treatment in 1928, at which time a stippled blue line on the gums was noted. In September, 1929, he complained of morning retching, central abdominal pain, and loss of weight. In January, 1930, he complained of abdominal pain and constipation, and was pale, wasted, and tremulous. In April, 1931, he had a return of abdominal symptoms, and was admitted to the Royal Devon and Exeter Hospital under the care of Dr. C. J. Fuller. He had typhoid in 1915, but had always been otherwise healthy. There is no history of headaches or fits. He began to drink cider in 1921, having previously been a beer-drinker. He admits to an average consumption of five pints daily, rising occasionally to ten pints daily. He obtains his cider from houses A, B, D, E, F, and G. He has, acting on advice, given up cider since his discharge from hospital, and has much improved. He was a healthy-looking, edentulous man, with a dull mentality. Blood pressure 140/95. There was slight wasting of the small muscles of both hands but no noticeable weakness and a fine tremor of the tongue and hands.

Laboratory findings.—Blood: punctate basophilia present. Urine: lead present, no albumin found.

---

[2] Opusculum de Morbo Colico Damnoniensi. Lond., J. Hinton, 1752.

[3] Med. Trans. Lond., 1772, i., 175.

evidence is brought forward to support the theory. Moreover, it is curious that in the first case recorded, the drill hole and graft were badly placed and instead of lying in the femoral neck, the graft is situated horizontally in the upper shaft of the femur at the level of the small trochanter; and yet it is claimed that there was complete restoration of joint movement, relief of pain, and a 90 per cent. improvement in the condition of the joint, which had been maintained when the patient was re-examined 12 months later. Ten cases are described in detail and all of the results are said to be satisfactory. In none of the cases has a sufficient period of observation been maintained to convince the reader that the improvement will be lasting. It is difficult to believe that simple drilling of the neck of the femur can permanently alter the vascular relationships of the bone, and since we know that transplanted beef bone is fairly rapidly absorbed, and the host bone restored to its original condition, it is not easy to see how drilling and grafting can give rise to more than a temporary alleviation of symptoms, even if it be accepted that the hyperæmia so induced does in fact give rise to the degree of improvement which is claimed.

A QUESTION OF ASSESSMENT

A PRACTITIONER asks whether he is entitled to deduct from his income-tax return some very heavy medical fees paid with the object of being kept fit for work—which would otherwise have been impossible. The point, we are informed, is dealt with quite definitely in the Income Tax Acts. Among the rules governing Schedule "D" is to be found one which states that no sum shall be deducted in respect of any disbursements or expenses of maintenance of the parties, or of any sums expended for private purposes distinct from the purposes of the vocation. The passage is somewhat involved and may be misread, but in practice it definitely excludes medical treatment of the tax-payer, although on common-sense grounds the retention or regaining of a healthy bodily condition might well be regarded as essential for professional work.

NATURAL RADIUM WATER

"A. B.," having read the article entitled Radium as a *Pharmaceutical Poison, by Dr. H. A. Colwell* and Prof. Sidney Russ, in THE LANCET of July 23rd (p. 221), writes to ask whether the continued internal use of natural radium waters, or of water containing thorium, is devoid of risk, especially the risk of provoking cancer. We are assured that there is no evidence to show that any body of people have been harmed by drinking pure natural waters which contain radium and thorium. The references in the article mentioned were to the occurrence of sarcoma following the drinking of water in which the natural radio-active content had been artificially raised. Presumably if it had been raised with thorium to the same radio-active degree as with radium the results would have been similar, but there seems no reason for apprehension where a natural product is in question.

EARLY SIGNS OF MAJOR MENTAL DISORDERS

AT a meeting of the Paddington Medical Society, held on Sept. 13th, Dr. Frederick Dillon spoke of Early Signs of Major Mental Disorders from the point of view of the practitioner. He said that such early symptoms as depression, excitement, and insomnia were apt to be overlooked owing to their protean character and the circumstances under which general practice had to be carried on. They were, however, of great significance, and at a time when a patient was still engaged in a struggle to preserve his normal reactions, were liable to be productive of serious consequences. Early depression at a stage when the psychomotor functions were still active might easily end in suicide. The early stages of excitement might lead an individual into antisocial or other misdeeds of serious consequence. Insomnia was never a pathological condition in itself: it was the signal of a more far-reaching state of mind. Dr. Dillon compared the relative value of hypnotic drugs in the early psychoses, and expressed the opinion that the danger of habit formation might easily be exaggerated. In the discussion which followed, Sir John Collie deplored the tendency to overstress the medico-legal difficulties of certification. The "stigma" involved in certification might sometimes be best overcome by ignoring it. In any case early treatment might demand certification, and practitioners should not shirk their responsibilities in this respect.

A WARNING

WE are asked by the Chief Constable of South Shields to draw attention to a man who represents himself as "*Dr. John Alexander Tolmie.*" This man is said to be identical with Andrew John Gibson, who has a number of convictions for obtaining money by fraud, &c., in New South Wales, at San Quentin (California), San Francisco, Durban, and Johannesburg, and at the Hants Assizes (from Bournemouth). In South Shields he got into conversation with a local practitioner, and was introduced by the latter to his bank manager, to whom he presented a bogus deposit certificate demand note for $10,000, drawn on the Provincial Treasurer's Office, Edmonton, Canada, and was given a cheque book containing 30 cheques, Nos. H/2 A. 17731 to 17760 (inclusive). He cashed a number of cheques and is now wanted on warrant. He also entered into an agreement for partnership with the local doctor.

"Dr. Tolmie," is described as: aged 52 years, height 5ft. 7½ in., complexion fresh, hair grey, eyes grey, small cyst on right side of face, indistinct dot on right forearm. It is desired that should he visit any practitioner information be immediately given to the local police.

INTERMITTENT HEADACHE IN WOMEN.—We are asked to state that the œstrogenic hormone isolated from the placenta and physiologically standardised by Prof. J. B. Collip at McGill, under the name emmenin, may be obtained directly in this country from the Glaxo Laboratories, 56, Osnaburgh-street, London, N.W.1.

ESSEX COUNTY HOSPITAL, COLCHESTER.—The Bishop of Chelmsford last week dedicated the chapel in the new nurses' home, which has been erected in memory of the late Mrs. Leeston Smith.

YORKSHIRE CRIPPLE CHILDREN'S HOME.—This home, which is situated at Kirby Moorside, has established a factory for the manufacture of the surgical appliances needed by the patients.

PLYMOUTH PAYING PATIENTS AND INSURANCE SCHEME.—A scheme with this title, sponsored by Plymouth Voluntary Hospitals Committee, will come into operation on Nov. 1st. It owes its inception to the desire of many persons who are debarred by the income limit from participation in the local penny-in-the-pound scheme. The plan is intended to assist people to pay the costs of their medical and surgical attention in any medical institution "if accepted at any such institution, whether in the general or private wards of a voluntary hospital or in a nursing home." The nursing home or hospital used must be fully recognised by the committee, and certain illnesses will be excluded. There is no income limit, residence in the Plymouth area is not a necessary qualification, and any recognised institution in the United Kingdom can be used. The annual subscription is a guinea a year, and the benefits are as follows: (*a*) £6 a week up to a maximum of four weeks towards costs allowed for an operation or serious illness in a voluntary hospital; (*b*) not exceeding £6 a week up to a maximum of four weeks towards costs allowed in a nursing home for an operation; (*c*) grant towards cost of maintenance as approved by the committee up to £6 per week for four weeks for a serious illness other than an operation in a nursing home. The maximum benefit in any one year is: Group A, single person, £26; group B, family of two, £60; group C, for each additional member over two in family, add £12. General practitioners' fees are not included.

liminary step, two houses (B and C) were investi- ed, in which the cider was known to be drawn m cask to engine through 12 to 16 ft. of lead ing. In each case a sample of cider was taken ect from the cask—i.e., as supplied by the manu- turer—and proved, on analysis, to be lead-free. each case, also, a sample of cider was drawn from e engine early in the morning, thus ensuring its ving been in contact with the lead pipe all night. th these samples proved, on analysis, to contain 15 gr. per gallon of lead. In consequence of this, d in accordance with instructions from the county edical officer of health, all the houses in the area ere warned to desist from using lead pipes for rawing cider. Some months later it was brought our notice that four publicans (houses, A, D, G, nd I) were still drawing cider through lead pipes ned with tin. They had been assured by the makers f such pipes that absorption of lead could not occur rom them, and that they were perfectly safe cider onductors. To test this assertion, samples of cider ere collected from the engines of the four houses n question. In all these cases the cider was drawn n the afternoon, after it had been standing in contact with the tin-lined pipes for three hours. Analysis f these four samples revealed the presence of lead n all of them in amounts varying from 1/20 to /10 gr. per gallon. Samples of cider taken direct rom the wood in these four houses were lead-free. In the remaining houses in this town (E, F, H, and J) he cider was known to be drawn direct from the wood. The facts concerning the village house K are suggestive but not conclusive. Cases 9 and 10 came from the same village, and were in the habit of drinking cider at the same public-house K. The publican, on being questioned, maintained that it was his invariable custom to draw cider direct from the wood. A sample of this cider was accordingly analysed and found to be lead-free. Since, however, both patients insisted that they had been served at this house with cider drawn through an engine, further discreet inquiries were made in the neighbourhood which elicited evidence in support of their statements. Nevertheless, the charge must remain non-proven, since no sample of engine cider could be obtained for analysis. The cider in house L, which was known to be drawn straight from the wood, was not investigated.

Analysis of Cider for Lead

House.	Patients frequenting.	Method of drawing cider.	Make of cider.	Result of analysis for lead:—Cider from cask: nil in all samples examined. Cider through pipe (gr. per gallon).

NOTE ON METHOD OF ANALYSIS OF CIDER FOR LEAD

The detection and quantitative estimation of lead *in all the above samples of cider* was carried out by Mr. Thomas Tickle, public analyst to the county of Devon, whose assistance we desire gratefully to acknowledge. The process he used was to remove organic matter by oxidation with nitric acid in the presence of concentrated sulphuric acid. After evaporating the sulphuric acid to eliminate the effect of iron by the method described by R. Wilkie[6] he matched the colour produced by sodium sulphide with that given in like association by a known quantity of lead.

Summary.

1. The occurrence of a small outbreak of lead colic in a Devonshire town is recorded.
2. The source of lead in the cider causing this outbreak was found to be the conducting pipes used in certain public-houses to draw cider from cask to engine.
3. Clinical notes are given of ten cases with symptoms. The following characteristics were common to all: attacks of colic and constipation; a stippled blue line on the gums; punctate basophilia; excretion of lead either in the urine or fæces. Four cases had muscular weakness or wasting, with tremors. In three cases the abdominal symptoms were so severe as to warrant a diagnosis of acute intestinal obstruction, and in one case the abdomen was explored. Albuminuria was found in two cases. No further acute symptoms of lead poisoning were observed after the patients had been warned against drinking cider drawn from the engine.
4. Clinical notes are given of three symptomless cases. Of these, two had a stippled blue line on the gums, two were excreting lead in the urine, and one had punctate basophilia.
5. Eleven public-houses were investigated. In six of these lead was found in the cider as drawn by the bar engine, though samples from the cask were in all cases investigated free from lead.
6. None of the cases coming to our notice occurred among pure beer drinkers, although lead pipes have been, and in some cases still are, used for conducting beer. This points to the conclusion that cider is a more active solvent of lead than is beer, owing to its greater acidity.
7. We would also suggest that the acidity of cider tends to keep the lead mobilised in the tissues, and therefore liable to produce symptoms of plumbism more readily than similar quantities ingested in a more alkaline medium, such as water or beer.
8. The occurrence of this outbreak shows that the possibility of plumbism from this source should always be kept in mind in cider-drinking areas.

In addition to Mr. Tickle, our thanks are due to Dr. Donald Hunter for his persistent help and encouragement; to Dr. W. Robb, pathologist to the Royal Devon and Exeter Hospital, for allowing one of us to use his laboratory and apparatus, and for his skilled help and advice; to Dr. Horton Date, assistant county medical officer of health; to Dr. H. F. L. Hugo, the local medical officer of health; and to Drs. Roper, Fuller, and Seward, of the Royal Devon and Exeter Hospital, for allowing us access to their patients and case notes. A word of praise is due to the patients, many of whom allowed themselves to be investigated in spite of being free from symptoms at the time; and finally to the publicans, who coöperated in a public-spirited manner.

---

[6] Jour. of the Soc. of Chem. Industry, 1909, xxviii., 636.

CASE 4.—G. H., aged 70, a farm labourer, had attacks of giddiness and an irregular pulse in 1921. In 1922 he had dyspnœa, tachycardia, and a fainting attack. In 1925 dyspnœa and tachycardia were again noted. In July, 1930, he had an attack of acute intestinal obstruction; was admitted to hospital, where a laparotomy was performed. Nothing was found to account for his symptoms, and he made an uneventful recovery. In October, 1930, he had an attack of colicky abdominal pain, and constipation relieved by enemata. A month later he had another similar attack. In January, 1931, he had a further attack, and a stippled blue line noticed on the gums. He was warned off cider, and has been free from symptoms since. There is no history of headaches or fits. He has been a moderate cider-drinker all his life, and admits to one pint daily, obtained from either house C or house D. He was a fairly healthy-looking old man, with a slightly tremulous, furred tongue. A stippled blue line was present on the gums. Blood pressure 130/90. There was a fine tremor of hands and some wasting of both thenar eminences. He has noticed slight weakness of both wrists, the left more so than the right. He is a left-handed man.

Laboratory findings.—Blood: very occasional red cells showing punctate basophilia. Urine: small amount of lead present, no albumin.

CASE 5.—I. J., aged 48, a labourer, had an attack of colicky abdominal pain and constipation in 1922. He had further similar attacks in 1923, 1929, and 1930. A stippled blue line on the gums was noted in 1929. There is no history of headaches or fits. He has drunk cider for the last ten years and admits to three or four pints daily, which he obtains from houses A, C, D, E, F, and G. He used to have the first drink at 11 A.M., but latterly has studiously avoided doing so. He was a healthy-looking man with a slightly furred tongue. A stippled blue line on the gums was present. Blood pressure 140/85. No other abnormality found.

Laboratory findings.—Blood: punctate basophilia present. Urine: lead present, no albumin.

CASE 6.—K. L., aged 33, a labourer, has had several attacks of colicky abdominal pain and constipation since February, 1931. There is no history of headaches or fits nor of any other illness. He has been a cider-drinker all his life, and admits to two or three pints daily which he obtains from houses E, F, and G. He never drinks cider before 6 P.M. Nothing abnormal was found except a stippled blue line on the gums. Blood pressure 140/90.

Laboratory findings.—Blood: punctate basophilia present. Urine: lead present in small amount, no albumin.

CASE 7.—M. N., aged 36, a labourer latterly employed as cleaner at house C, had two attacks of colicky abdominal pain, vomiting, and constipation, each lasting for about a week in January and February, 1931. In May, 1931, he had a third attack which was more severe and lasted a fortnight. There is no history of headaches or fits. In 1918 he was invalided out of the Army with "stomach trouble." He has drunk cider regularly since 1918. He admits to three pints daily, and frequents all the houses in the town. He used to have the first drink in the morning till warned against it in 1931. He was a somewhat pale, under-sized man. Nothing else abnormal was found except a stippled blue line on the gums. Blood pressure 130/85.

Laboratory findings.—Blood: films unsatisfactory. Urine: lead present, no albumin.

CASE 8.—O. P., aged 41, a sawyer, had several attacks of colicky abdominal pain, constipation, and vomiting in 1930. In May, 1931, he had a fit which came on suddenly without warning; he was seen to throw his head up, spin round, and fall. When seen immediately afterwards by one of us (L. N. J.) he was pale, twitching, and foaming at the mouth. He had bitten his tongue, was vomiting repeatedly, and complaining of intense headache. An hour later he had recovered almost completely. There was no previous history of headaches or fits or of any other illness. He has been a cider-drinker all his life, and admits to five or six pints daily, which he obtains from houses B, C, E, G, H, and I. He habitually has a drink at 11 A.M., and often has the first drink drawn.

On examination after recovery from the fit he had a good colour. There was a stippled blue line present on the gums and a fine tremor of the tongue and hands. Blood pressure 140/90. No other abnormality found.

Laboratory findings.—Blood: punctate basophilia present. Urine: lead present in considerable amount, no albumin.

The remaining two cases in this group do not belong to this town, but come from a village some ten miles distant. They were admitted to the Royal Devon and Exeter Hospital under the care of Dr. Frank Roper and Dr. Charles Seward respectively.

CASE 9.—Q. R., aged 56, a platelayer, has had repea attacks of colicky abdominal pain and constipation si 1927. Barium X ray investigation in 1927 and again i 1931 revealed no cause for his symptoms. The attack became more severe and, in the most recent attack, h vomited. He was admitted to the Royal Devon a Exeter Hospital as a case of acute intestinal obstructio but the diagnosis was revised in time to save him fro operation. There is no history of headache, fits, muscul weakness, or any previous disability. He has drunk cid all his life, and admits to two pints daily, which he invariabl obtains from house K. When examined he was not pal A stippled blue line was present on the gums. Blood pressure 120/90. No other abnormality found.

Laboratory findings.—Blood: red cells 4,000,000 per c.mm., hæmoglobin 46 per cent., punctate basophilia present. Urine: lead present, no albumin.

CASE 10.—S. T., aged 59, a farm labourer, has durin the last year had two severe attacks of colicky abdomin pain and constipation, each lasting from two to three day In the second attack he vomited, and was admitted to th Royal Devon and Exeter Hospital as a surgical emergency No operation was performed. There is no history of head aches, fits, or muscular weakness. He has been a cide drinker for one year, and admits to two to three pin daily, which he obtains from houses K and L. He stat that the cider is drawn through an engine in house K, b that it comes straight from the wood in house L. Wh examined he was not pale. A doubtful stippled blue li was present on the gums. Blood pressure 125/85. No oth abnormality found.

Laboratory findings.—Blood: punctate basophilia prese Urine: lead present, no albumin.

2. SYMPTOMLESS CASES

CASE 11.—U. V., aged 39, a golf club steward and barm had ascites in January, 1931, which was thought to be d to portal cirrhosis, and which cleared up completely two months without special treatment. He had a "nerv breakdown" three years ago, and an injury to the seven cervical vertebra during the war. This resulted in wea ness of the left arm and right leg, on account of wh he was invalided out of the Army. There is no history headache or fits. He admits to having drunk four pi of cider daily since 1918 until he developed ascites, si when he has substituted beer. He frequents houses A, and D. He was a pale, thin, slightly built man, with cari teeth and a doubtful stippled blue line on the gums. Th was a fine tremor and wasting of the small muscles of b hands, especially the left. Blood pressure 120/80. No ot relevant abnormality found.

Laboratory findings.—Blood: punctate basophilia present. Urine: no lead, no albumin.

CASE 12.—W. X., aged 30, a labourer, has no medi history. He admits to two to six pints of cider daily. usually has his first drink at 11 A.M., and sometimes the first drink drawn. He frequents houses A, B, E, and G. On examination nothing abnormal was fou except a fine tremor of the hands. Blood pressure 140/

Laboratory findings.—Blood: punctate basophilia present. Urine: a trace of lead present, no albumin.

CASE 13.—Y. Z., aged 64, a general labourer, has medical history. He admits to six pints of cider da all obtained at house A. There was a stippled blue on the gums round his few remaining teeth. Bl pressure 140/80. No other abnormality found.

Laboratory findings.—Blood: slight punctate basoph Urine: lead present, no albumin.

NOTE ON LABORATORY METHODS EMPLOYED

The blood films were fixed with methyl-alcohol stained with Unna's alkaline methylene-blue soluti For the detection of lead in the urine, L. T. Fairh chromate method was used [4]; five or six days' outpu urine being collected under toluol in each case. The e mations were not carried further than the stage of cipitation of lead chromate and are therefore only qualitat Every urine was also examined by J. C. Thresh's sulph method,[5] and the results were comparable.

Examination of Public-houses and Cider

Eleven public-houses came under suspicion. of them are in this town, the eleventh in a vill ten miles away. Inquiries into the methods of ci storage and supply to consumers were made in cases, but it was not found practicable to obt samples of cider for analysis in every case. As was admitted after a severe hæmatemesis in a collapsed ition; he made a good recovery, and the bleeding ped, but the ulcer perforated on July 15th, and he died he operating table before the operation was started. ost mortem.—A large perforation of a very large, chronic, lle-shaped ulcer of the lesser curvature.

---

[4] Medicine, Baltimore, 1925, iv., 1.

[5] The Analyst, 1924, xlix., 124.

'oman, aged 56. Admitted Nov. 13th, 1928; died . 21st. She gave a two years' history suggesting a ric ulcer, and she was admitted three days after a re hæmatemesis; her progress was satisfactory until rforation of the ulcer occurred on Nov. 21st; she died after operation. *Post mortem* showed perforation large and very chronic ulcer on the middle of the r curvature of the stomach, complicated by general tonitis.

an, aged 49. Admitted June 18th, 1926; died June 30th. gave a long and rather indefinite history of dyspepsia, was admitted with hæmatemesis and melæna of a k's duration. He did very well, but 12 days after ission he had a fit, collapsed, and died in coma in eight rs. *Post mortem.*—The stomach showed three ulcers, almost encircling the organ and starting at the greater vature, a second near the cardia, and healed, and a d on the greater curvature proximal to the first with eroded vessel in its base. The left kidney showed ensive tuberculous disease, and miliary tuberculosis was sent with tuberculous meningitis.

lan, aged 58. Admitted March 9th, 1927; died rch 13th. The patient had a history of a duodenal ulcer two years; he was admitted blanched after a hæmatesis, and in spite of this his blood pressure was 230/170. bleeding proved to be uncontrollable, and he died. *t mortem.*—A circular chronic ulcer was found in the t part of the duodenum, with an eroded vessel at its e; the kidneys showed an advanced condition of primary nular contracted kidney.

Corrected mortality.—In reckoning the mortality m the point of view of hæmatemesis, it would seem missible to exclude the two cases of perforation, l the case of tuberculous meningitis. This would e a corrected mortality as follows:—

72 cases with 8 deaths—mortality 11·5 per cent.
50 males „ 7 „ — „ 14 „
22 females „ 1 death— „ 4·5 „

The sites of the ulcers in the fatal cases were as lows: no autopsy, 1 case; duodenum, 2 cases; ser curvature, middle, 3 cases; cardia (3 ulcers), case; greater curvature, near cardia, 1 case; sophagus and pylorus, 1 case; pylorus, 2 cases.

Chronic gastric and duodenal ulcers.—On clinical d other grounds the following differentiation was ade:—

	Cases.
Gastric ulcers (X ray, operation, or autopsy confirmation)	24
Gastric ulcers (clinical diagnosis without confirmation)	34
Duodenal ulcers (X ray, operation, or autopsy confirmation)	9
Duodenal ulcers (clinical diagnosis without confirmation)	5

The age- and sex-incidence is set out in Table IV.

ABLE IV.—*Age- and Sex-incidence of Chronic Ulcers*

ACUTE AND CHRONIC ULCERS TOGETHER

The gross mortality from acute and chronic ulcers, 926–31, was as follows:—

Total cases, 111; deaths, 18; mortality, 16 per cent.
Males, 80; „ 14; „ 17·5 „
Females, 31; „ 4; „ 12·9 „

The corrected mortality, reached by exclusion of two deaths from perforation and one death from tuberculous meningitis, was as follows:—

Total cases, 111; deaths, 15; mortality, 13·5 per cent.
Males, 80; „ 12; „ 15 „
Females, 31; „ 3; „ 10 „

Severity of the hæmorrhage.—In Table V. the cases have been separated into those admitted in the first attack of hæmatemesis and those who gave a history of previous attacks; the classification, according to the severity of the bleeding, is somewhat arbitrary.

TABLE V.—*Severity of Hæmorrhage*

Severity of bleeding.	Cases.	
	First attack.	History of previous attack.
Fatal	17	2
Collapsed on admission ..	18	2
Severe	52	9
Moderate or slight ..	10	1

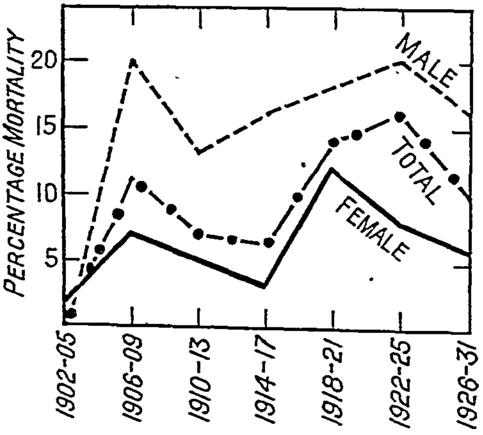
HÆMATEMESIS IN PEPTIC ULCER

The mortality from hæmatemesis in peptic ulcer (1902–31) may be summarised as follows:—

Total cases.—Of 578 cases, 66 died; excluding 3 deaths from perforation and 1 death from tuberculous meningitis, the mortality is 10·7 per cent.

240 males with 39 deaths—mortality, 16·2 per cent.
338 females „ 23 „ — „ 6·8 „
Acute cases—
257 cases with 25 deaths—mortality, 9·7 per cent.
101 males „ 17 „ — „ 16·8 „
156 females „ 8 „ — „ 5·1 „
Chronic cases—
321 cases with 37 deaths—mortality, 11·5 per cent.
139 males „ 22 „ — „ 15·7 „
182 females „ 15 „ — „ 8·2 „

The percentage mortality from hæmatemesis, 1902–31, is illustrated in the Figure.



Percentage mortality from hæmatemesis, 1902–31.

TREATMENT

It was not possible to account for a low or a high mortality by differences in treatment; the methods adopted appear to have been fairly constant at each stage, and did not differ from the treatment used at other centres. At the present time the treatment is morphine, a period of starvation with rectal salines, and later a graduated diet with alkalis. Blood transfusion has been frequently resorted to when the bleeding has persisted or other indications have presented themselves. Two cases were submitted to

MORTALITY FROM HÆMATEMESIS

A SUPPLEMENTARY ANALYSIS

By Ernest Bulmer, M.D. Edin., M.R.C.P. Edin. & Lond.

ASSISTANT PHYSICIAN, GENERAL HOSPITAL, BIRMINGHAM

In 1927 I recorded[1] the mortality of all cases of hæmatemesis admitted to the medical wards of the General Hospital, Birmingham, between January, 1902, and July, 1926; the present investigation covered the period between August, 1926, and December, 1931. In both of these series every case admitted to the medical wards on account of hæmatemesis has been included, and in the present series three cases in which a hæmatemesis occurred soon after admission. Many cases who are admitted for the treatment of a peptic ulcer give a history of the vomiting of "coffee-grounds," or even of a small quantity of blood—these cases do not come within the scope of the inquiry; this point is an important one, and it is particularly to be noted that my results show the mortality of cases for whom admission to hospital is sought, as medical emergencies, for the treatment of hæmatemesis as the leading, often the only, symptom.

A summary of the 1902–26 series is given in Table I.

TABLE I.—*Cases of Hæmatemesis, 1902–26*

Disease.	Cases.			Deaths.			P.M.'s.
	M.	F.	Total	M.	F.	Total

Doubtful cases ..	..	..	24	..	..	3	2
Total			526			67	53

The peptic ulcer group (1902–26) may be analysed as follows:—

Acute ulcers.—Of 218 cases, 19 died—excluding one death which was due to perforation and peritonitis the mortality was 8·3 per cent.; the males showed a mortality of 16·9 per cent.; females, 3·1 per cent.

Chronic ulcers.—Total mortality of 11·6 per cent.; males, 16·8 per cent.; females, 8·7 per cent.

Total ulcers.—Total mortality of 10·7 per cent.; males, 16·8 per cent.; females, 6·5 per cent.

A corresponding summary of the 1926–31 series is given in Table II.

TABLE II.—*Cases of Hæmatemesis, 1926–31*

ACUTE ULCERS, 1926–31

No attempt has been made to differentiate acute gastric from acute duodenal ulcers on clinical grounds, the evidence from the post-mortem room is included.

Mortality in acute ulcers.—There were 7 deaths in the 39 cases—a mortality of 18 per cent.; of 30 males, 7 died—a mortality of 16·6 per cent.; of the 9 females, 2 died—a mortality of 22·2 per cent.

Cause of death: hæmorrhage alone, 4 cases; secondary broncho-pneumonia, 1 case; hæmorrhage with unsuccessful surgical treatment for its arrest, 2 cases.

Site of ulceration: no autopsy, 1 case; duodenum, 2 cases; lesser curvature, middle, 3 cases; pyloric antrum near greater curvature, 1 case.

Notes on the cases treated surgically.—The difficulties of surgical treatment are sufficiently emphasised in the case notes:—

Boy, aged 17. Admitted Sept. 10th, 1931; died Sept. 17th. He gave a rather indefinite history of pain after food for three months; he was admitted on account of a profuse hæmatemesis, and treated by starvation, rectal salines, and morphine; as the bleeding persisted a blood transfusion was given, and the bleeding stopped It soon started again, and he was submitted to an operation. No ulcer could be identified externally, so the stomach was opened in the region of the pyloric antrum; a small area of thinned mucosa was found and invaginated. The bleeding persisted, and the patient died of it.

Post mortem.—Stomach: on the anterior surface there was an area of hæmorrhage covering the region of the exploratory incision, and the pyloric region had been sutured *but not in the region of the ulcer,* which was found only after searching very carefully on the anterior surface near the greater curvature; it could only have been found if the edges of the incision had been everted. There was no thickening, and it was impossible to palpate it from the outside or the inside, and by no means easy to find it at the autopsy. The ulcer was shallow, 1·2 by 0·8 c.cm., extending through the mucosa, and the central part extended into the submucosa, a small mass of fibrin covered two openings—the severed ends of a small artery.

Man, aged 49 years. Admitted Sept. 1st, 1931; died Sept. 5th. He gave a short history of dyspepsia, and was admitted after a profuse hæmatemesis; he rapidly got worse under the usual medical treatment, and was submitted to a laparotomy after a blood transfusion. The surgeon found a small thickened duodenal ulcer which he invaginated, but the patient died.

Post mortem.—Stomach: immediately beyond the pylorus there was a small and quite superficial acute duodenal ulcer extending down to the submucosa, a branch of the gastro-duodenal artery in its floor was eroded.

Age- and sex-incidence is set out in Table III.

TABLE III.—*Age- and Sex-incidence of Acute Ulcers*

Ages.	Under 20	21–30	31–40	41–50	51–60	61–70
Males	2	8	7	8	4	1
Deaths	1	0	1	2	1	0
Females	0	2	2	3	1	1
Deaths	0	0	2	0	0	0
Total	2	10	9	11	5	2
Deaths	1	0	3	2	1	0

CHRONIC ULCERS, 1926–31

Mortality.—Out of a total of 72 cases, 11 died—a mortality of 15·2 per cent. Of the 50 males, 9 died—a mortality of 18 per cent. Of the 22 females, 2 died—a mortality of 9 per cent.

Cause of death: hæmorrhage alone, 6 cases; cerebral thrombosis, 1 case; perforation, 2 cases; tuberculous meningitis, 1 case; hæmorrhage in a patient with chronic nephritis, 1 case. Some amplification is needed to justify the inclusion of one of these cases and the omission of three of them in arriving at the correct mortality from *hæmatemesis.*

Man, aged 49. Admitted July 8th, 1926; died July 15th He gave a history of gastric ulcer of five years' duration seriously considered. While I do not suggest that discriminate operative treatment should again be roduced in all cases of severe gastric hæmorrhage, s obvious from the above figures and post-mortem dings that in the group of cases presenting a 74 cent. mortality, operative interference in carefully ected cases might have improved the recovery-rate.

---

[1] THE LANCET, 1927, ii., 168. An error crept into the summary of this paper—the mortality from acute gastric ulcers in females was given as 8·7 per cent. instead of 3·1 per cent.

My thanks are due to Prof. O. L. V. de Wesselow help and encouragement, and to the staff of St. omas's Hospital for allowing me to publish these ures.

ITAMIN-A CONTENT OF THE LIVER IN PUERPERAL SEPSIS

By Harry N. Green, M.D., M.Sc. Sheff.

THE DEPARTMENT OF PHARMACOLOGY IN THE UNIVERSITY OF SHEFFIELD

In the course of an investigation [1] [2] into the effect treatment of cases of puerperal sepsis with con- trated preparations of vitamin A, the vitamin-A ntent of the liver was determined in those cases ming to autopsy.

It soon became obvious that under these conditions e liver was often fairly rich in this vitamin, but casional very low values, in spite of the ingestion large quantities of the vitamin, gave a more finite interest to the work. In the absence of y detailed figures as to the vitamin-A content of e livers of normal individuals, it was, however, fficult to assess the significance of the findings. is obviously impossible to use healthy puerperal omen as a basis of comparison, but the investigations L. K. Wolff and T. Moore* provide some indication the vitamin-A reserves of the liver in normal people. vestigations previous to these had shown that wide riations in the vitamin-A content of the liver curred in disease, and the more recent work shows at similar variations also appear in the healthy. he general level of the vitamin-A reserves in health oes indicate, however, that such low values as were und in some puerperal cases of the present series ere abnormal.

Technique.—The vitamin-A content of the liver as determined by the antimony trichloride test the unsaponifiable fraction of the liver fat, the lue value being estimated in the Lovibond tinto- eter. The amount of vitamin A present is expressed the form of the blue unit used by Moore,[3] so that irect comparison with his findings is possible.

Cases Treated with Vitamin A

In Tables I. and II. the essential details in 20 cases f puerperal sepsis treated with vitamin A are given. he septicæmic and non-septicæmic cases are separated order to show that the vitamin-A reserves, where here was a general infection of the blood stream, ere not in general lower than where the infection as more localised.

The vitamin-A preparations given were an arachis oil olution of mammalian liver fat and a more concentrated unsaponifiable extract from another source of mammalian liver fat. The former preparation usually provided the bulk of the vitamin given. Both preparations were periodically tested by the antimony trichloride test. The figures given in the tables under the heading of "Amount of vitamin A ingested" are necessarily approximate, since they are based on a pharmaceutical dosage. The quantity of preparation given on the day of death is not included in the estimate. The total content of the liver in vitamin A was calculated, in those cases where the exact weight of the liver was not known, by assuming the weight of the liver to be 1700 g.

It will be noted that whilst those cases receiving the larger quantities of vitamin tended to show the greater degree of vitamin-A reserves in the liver, this relation is by no means absolute, and there are some very anomalous cases. Cases 2 and 6 (Table I.) are prominent in this respect, whilst the cases in Table II. are grossly irregular, the two cases which had received the greatest amounts of vitamin showing the least reserves. The most striking instance of this disparity between the amount of ingested vitamin and the amount found in the liver is Case 1 (Table II.), where, though 15,000,000 units were given, the whole liver contained roughly only 1000 units. Other examples of this failure of the liver to retain the ingested vitamin may easily be found.

In the whole 20 treated cases the average amount of vitamin A in the liver was only 15 per cent. of the average total amount taken by mouth—excluding the vitamin A in the general diet, which in many cases was considerable in amount. The actual amount of vitamin A retained by the liver must, however, have been much lower than this percentage figure would indicate, for it is very unlikely (vide values for untreated cases, Table IV.) that the liver was usually devoid of vitamin at the commencement of treatment. Assuming (vide infra) that 10 per cent. of the ingested vitamin is lost in the fæces, and that the average content of the liver was that of the group of untreated septic cases (Table IV.), the average amount of the absorbed vitamin retained by the liver is found to be 8 per cent.

In a few cases it seems possible that a much larger proportion of the vitamin was taken up by the liver. Prominent amongst these are Cases 7 (Table I.) and 6 (Table II.), but it may well be that in these instances the original content of the liver in vitamin A was relatively high *prior to the commencement* of treatment.

FATE OF THE INGESTED VITAMIN

It is thus obvious that either a large proportion of the vitamin preparation taken by mouth was not absorbed or, if absorbed, was rapidly excreted or destroyed. The question of absorption has not been fully investigated, but Rowntree[4] studied this question in children, using a biological technique for the estimation of vitamin A in the fæces, and came to the conclusion that absorption depended upon the absorption of fat. The loss of vitamin A in the fæces varied from 2 to 12 per cent., the largest loss occurring with the largest intake. The fæcal content of vitamin A was estimated in two cases of the present series, and the loss by this route estimated at about 5 per cent., but no particular attention was paid to this point at the time, for its significance was not then realised. Further work is in progress on the question of alimentary excretion of vitamin A in cases of sepsis, and the preliminary results do not indicate a very large loss in this way. Failure to absorb the vitamin is therefore not likely to account for anything but a relatively small fraction of the unrecovered vitamin in the puerperal cases.

There is little evidence that urinary excretion accounts for any significant loss. Experiments in dogs operation with fatal results; in one case gastric lavage was used and the patient recovered.

---

* Dr. Moore's paper appeared in our last issue. Prof. Wolff's as published on Sept. 17th (p. 617).

COMMENT

I wish to make no comment on the figures in this paper; I was led to bring the 1902–26 series up to date in order to see whether the mortality had changed; but with a much smaller series it appears that the difference is not marked. In Birmingham over a period of 30 years the experience of one hospital suggests a mortality in hæmatemesis from peptic ulcer of about 10 per cent.—the death-rate among men being at least double that among women, and occurring at rather a later age-period.

Finally, I must express my thanks to the members of the honorary medical staff of the General Hospital, Birmingham, for allowing me to publish the cases.

MORTALITY OF SEVERE HÆMORRHAGE FROM PEPTIC ULCERS

By W. E. Chiesman, M.B. Camb., M.R.C.P. Lond.
FIRST ASSISTANT, MEDICAL UNIT, ST. THOMAS'S HOSPITAL

Peptic ulceration of the stomach is likely to be attended by several complications, each of which calls for urgent treatment if the patient's life is to be saved. It is not sufficiently recognised that, apart from perforation or occlusion of the pylorus by scar tissue, there is a very considerable proportion of cases in which persistent or gross hæmorrhage is the direct cause of death, and there appears to be no unanimity of opinion on the treatment of these patients. Hurst,[1] for instance, said at a discussion at the Royal Society of Medicine in 1924: "I believe that hæmorrhage from gastric and duodenal ulcers is far less often fatal than is generally supposed. I have never had a case under my care in which death resulted, although I have only once had to call in the aid of a surgeon to save the patient's life." He reaffirmed this in 1929.[2] Paterson,[3] at the same discussion, in dealing with collected statistics of London hospitals, found a mortality from hæmorrhage of 3·8 per cent. in 1343 medically treated peptic ulcers, and admitted a probable mortality of 11·8 per cent. in severe hæmorrhage. At the same time he stated that he had yet to see a death from hæmatemesis *from a gastric or duodenal ulcer.* On the other hand, Hinton [4] records a mortality of 20 per cent. in 52 cases of gross hæmorrhage at the Bellevue Hospital, New York; Ross [5] 58 per cent. in 45 cases treated medically in Melbourne; and Lynch [6] 12·9 per cent. in 31 cases of gross hæmorrhage under medical treatment. There are, therefore, considerable differences of opinion as to the mortality-rate from this complication of peptic ulcer.

I have analysed all the cases of peptic ulcer and its complications admitted to St. Thomas's Hospital during the period 1925–31 inclusive; these included simple gastric, duodenal, and jejunal ulcers, perforated ulcers, and pyloric obstruction from scarring. The mortality from all causes in proved peptic ulcers was 11·3 per cent. in 1410 males and 8·4 per cent. in 402 females, representing a total mortality of 10·8 per cent.

Admissions for gross hæmorrhage, requiring urgent attention owing to sudden loss of blood by hæmatemesis or by the bowel, numbered 137 males and 54 females; hæmorrhage was the predominant feature in each of these cases. The mortality in patients admitted for hæmorrhage was 27 per cent. in males and 15·6 per cent. in females—a total mortality of 25 per cent., equivalent to that of perforated ulcers in this group. All these cases of hæmorrhage were treated by medical means, including complete rest, rectal salines, and morphia; about one-quarter received alkalis by mouth; 15 cases were transfused. Various hæmostatics were used in a number of cases without any convincing results. Washing out of the stomach with ice-cold water, as advocated by Hurst,[1] was not, however, adopted in any case. In view of these figures it is impossible to regard the medical treatment employed as entirely satisfactory. When we come to consider the advisability of calling in the surgeon there is, in view of the patient's general condition, a natural hesitation. Exsanguinated patients, even when transfused on the table, are a bad operation risk.

INDICATIONS FOR SURGICAL TREATMENT

The question therefore arises: is there any indication of the type of case in which medical treatment is likely to fail? As far as my figures go, it is exceptional for a single hæmorrhage from a peptic ulcer to lead to death. The striking fact about the fatal cases is that in all of them the hæmorrhage continued or recurred after admission to hospital, in spite of medical treatment. When hæmorrhage was still continuing, or recommenced after 24 hours of treatment, it indicated that a bleeding point was present which could not readily be occluded by medical means.

Of the admissions for gross hæmorrhage, bleeding continued or recurred 24 hours after coming under treatment in 48 male and 14 female cases; of these, 38 males and 8 females died, a mortality of 74 per cent. Post-mortem examinations on 45 of these patients revealed that the common cause of repeated hæmorrhage was a partially eroded vessel of considerable size in the floor of an ulcer, the type of ulcer being callous in 30 cases and acute in 7 cases; multiple ulcers were present in the other cases. The site of the ulcer was in the stomach in 31 cases, in the duodenum in 8 cases, and at the pylorus in 6 cases. One case showed both a callous ulcer in the duodenum and an acute lesion, with bleeding, in the stomach; whilst in another the pathological examination *revealed no definite bleeding point,* death being attributed by the pathologist to gastrostaxis. Eleven of these cases were under 40 years of age, with 7 deaths; 40 were between 40 and 60, with 28 deaths; while 11 cases over 60 years were all fatal. Four cases were complicated by parotitis, 1 by pneumonia, and 2 by aortic aneurysm.

The duration of dyspeptic symptoms was very variable. The shortest history among the fatal cases was only three days, but many had a history of ten years or more. In some cases, where the history was of only a few weeks, the ulcer was reported by the pathologist to be of the chronic type, while in others with a long history the hæmorrhage appeared to have arisen from an acute superficial ulcer. In most cases the hæmorrhage continued for several days, and in one case there was continued bleeding *for one month before death; the shortest time* from the onset of hæmorrhage to the death of a patient was 48 hours. There was, therefore, ample time for surgical interference in all the fatal cases if it had been considered desirable.

In general, medical treatment should be given a fair trial in cases of severe gastric hæmorrhage, provided there is a reasonable chance of its success and valuable time is not lost, but there certainly seem to be cases in which surgical intervention should

7	0	0	Eclampsia.

and men submitted to a diet very rich in vitamin A (*including large doses of cod-liver oil*), carried out by Cooper,[5] suggest that a little vitamin A may be found in the urine under these conditions, but Rowntree[4] found no evidence of alimentary vitaminuria in children, even when the diet was very rich in vitamin A.

It must be concluded therefore, that when very large amounts of vitamin A pass into the liver, the liver cell (at least in the septic cases which were examined) is unable to incorporate most of the vitamin before it is either destroyed in the liver or passes into the general circulation. In the blood stream it is probably rapidly oxidised, for there is now good evidence that relatively very small quantities of vitamin A are stored in organs other than the liver.

COMPARISON WITH EXPERIMENTAL RESULTS IN ANIMALS

This failure of the liver cell to take up rapidly large quantities of vitamin A is also to be observed in animals. In rats the liver content of vitamin A only rises in a gradual manner when amounts much in excess of its normal requirements are fed, and there is no sudden increase when extremely large amounts of the vitamin are fed. Even when the vitamin is given intravenously, the liver fails to retain much of the vitamin presented to it as the experimental details (typical of several similar experiments) given in Table III. illustrate.

TABLE III.—*Effect of Intravenous Inoculation of Vitamin A on the Liver Reserves of the Rabbit*

No. of rabbits.	b.u. injected (average).	Total b.u. in liver (average).
4 (healthy)	158,000	71,000
3 (severe general tuberculosis) ..	290,000	32,000
4 (healthy controls)	0	18,000

Injections of an emulsion of a vitamin-A liver concentrate were given over an average period of nine days in the healthy rabbits, and over a period of 55 days in the tuberculous animals. In the healthy rabbits about two-thirds of the injected vitamin was not found in the liver or body generally, whilst in the tuberculous rabbits the disparity was very marked, only about 5 per cent. (allowing for the control values) was recovered, which suggests either that the normal capacity of the liver cell to store the vitamin was injured by the infection (the liver itself was not infected), or less possibly that utilisation of the vitamin was much increased by the tuberculous infection.

Carotene, the precursor of vitamin A, was still more rapidly destroyed when given intravenously in the healthy rabbit, for less than 25 per cent. was recovered from the body 30 minutes after the injection.

In the human cases, of course, the interpretation of the results is complicated by the presence of a very severe infection, and there can be little doubt that the degenerated condition of the liver cells so commonly found in severe infections was responsible in varying degree for the marked inability of the liver to retain the vitamin.

I have found some experimental support for this view. When a group of rats were given huge doses of cod-liver oil for a period of over one year the liver content of vitamin A was found to reach high levels in many cases, but in some the content was relatively, and in a few actually low. The livers of the animals showing low reserves were always in an advanced state of fatty degeneration and infiltration, due to the toxic action of the excess cod-liver oil, and possibly, in some degree, to the tuberculous infection to which the rats were submitted.

Cases with Low Reserves of Vitamin A

In the whole series of 27 treated and untreated cases of puerperal sepsis (Tables I., II., and IV.) 8 had a vitamin-A content per g. of liver of less than 50 b.u. A striking fact is that 5 of these cases had received sufficient vitamin A by mouth to raise the liver content to high levels, provided it had been retained.

It is also to be noted, though in such a small number of cases the association may be accidental, that 5 of the 8 cases with low vitamin-A reserves had extensive septic thrombo-phlebitis. Only 2 out of the total 7 cases showing this complication in severe form gave a value of more than 50 b.u. per g. of liver, and even in these two exceptions the liver content was not high, particularly in view of the very large amounts of vitamin given by mouth. The significance of this latter point is more obvious when it is realised that in one exception (Case 2, Table I.), where the b.u. per g. were 205, this figure would have been 3228 if all the ingested vitamin had been retained, and in the other exception the figure would have been 1765 instead of the determined value of 88.

In two of the cases of thrombo-phlebitis associated with low vitamin-A reserves (1 and 2, Table II.) the liver was examined histologically, and in both cases there was extensive cell necrosis at the periphery of the lobule, together with marked fatty degeneration and infiltration, a condition which was particularly severe in one case (1). The complete failure of the liver to retain the vitamin, in this case, has been already noted.

That there may be some relation between extensive venous thrombosis and low vitamin-A reserves seems more possible in view of the findings of Moore, for in six cases noted in his series, three had livers completely devoid of vitamin A. Moreover, Wolff points out that the liver content was considerably below the average in seven cases of lung embolism occurring in his series.

A probable explanation of these findings is that the toxic or degenerated state of the liver cell due to the extensive infection of the systemic veins was responsible for its failure to retain the vitamin presented to it, so that the vitamin originally present was utilised by the body without the loss being rectified from the incoming supplies from the intestine. Another possibility is that the original vitamin-A content of the liver prior to the onset of disease was low, and this condition predisposed to venous infection and thrombosis. There seems, however, no obvious reason why vitamin-A deficiency should predispose particularly to this complication, but since one liver function was so disorganised the possibility that failure of some other liver function may be responsible for the onset or prolongation of a thrombosed condition of the large veins should be considered.

THE VITAMIN-A RESERVES IN PUERPERAL WOMEN

The findings in seven women who died of non-septic disease are given in Table V. The cases are too few to warrant analysis or comparison with the septic cases, but they are included as they show two instances of low vitamin-A reserves. In one, a case of eclampsia, the liver was devoid of vitamin A—possibly another instance of liver degeneration. The other is s noticed that in one case a small amount of gas ected into the pleural cavity might greatly upset physiological activity of the lung, whereas the ge amount of gas used in another case might seem have a passive action only, that of mechanical ssure. Later, we began to study and catalogue so-called accidents, and found that these extra- linary cases threw much light upon the physio- ical or pathological changes seen in ordinary rmal cases. We found that certain changes ok place in a small degree in ordinary A.P.T. ocedure, but to an extreme degree in cases ere a so-called accident happened. It was first ident that pressure therapy was not merely erapy by pressure, but that a physiological action followed the induction of A.P.T. in every se.

"ACCIDENTS" OF ARTIFICIAL PNEUMOTHORAX

The well-known accidents met with in the induction artificial pneumothorax are generally catalogued der the following headings.

1. *Pleural or pleuro-cardial reflex.*—A condition of ock, being a sequence of cause and effect. (In these ses the effect is altogether out of proportion to the parent cause.) In all cases of so-called pleural flex there is an immediate upset in the physiological ocesses in the lung as a tissue, together with the oduction of a disorder in the rhythm of respiration the lung as an organ. There may be an extreme ervous collapse and a sudden cardiac irregularity. ain may be present, but pulmonary œdema is ways produced.

2. *Gas embolism* was described in graphic phrase y C. Saugman at the International Congress of ledicine in London in 1913. Saugman pushed his eedle rather deep into the chest and the patient istantly died. Post mortem, Saugman found rupture f a bronchus and the vessel lying beside it, and gas ubbles in the vessels of the brain. In J. Crocket's ublished case death was not quite as sudden, and was ue, he thought, to an unfortunate "milking" of the ube of the apparatus by an assistant, which forced as into the chest before the needle-point was free in he pleural cavity. In all such cases there is shock, nd in most of the German cases published it is diffi- ult to decide whether death was due to shock or to mbolism.

3. *Dislocation of the mediastinum* follows the induc- ion of too large a quantity of gas into the pleural avity, thus producing an immediate dextra- or sinstra-cardia. Parry Morgan considers that puncture of the lung may cause a leakage of gas and add to the volume forced in from the gas cylinder. In such cases the compression of one lung may also compress the other lung and lessen the negative pull in that lung. The result of so interfering with the negative pressure, which is physiologically necessary, can be easily appreciated.

4. *Pulmonary œdema or congestion* occurs in all other accidents, but is mentioned separately because it often develops without any apparent sufficient cause, the lung being a vital organ and not a mechanical machine.

In the following examples, collected from a practice extending over 20 years, extraordinary cases are stressed because of the lessons they teach. Ordinary cases require less comment, but I am convinced that in all ordinary cases there is some upset in the lung tissues, and that the actions and interactions which follow are the main cause of improvement.

CASE RECORDS

CASE 1.—A girl of 19 years. Fragile in build, fine features. Mucous membranes pale and teeth small, in regular setting and free from decay; no enlargement of tonsils or glands of neck; hands long and thin; muscles small; joints capable of hyper-extension; hair abundant, lanular hair on forehead. Signs of activity both apices, but area of disease apparently limited. T.B. present in sputum. Heart small. Pulse quick. Night temperature above 100° F.

It was considered, after X ray and other examinations, that gross disease was limited in area but that there was miliary spread. It was decided to try A.P.T. for the right (the worse) lung. The result at first was good; symptoms and signs decreased and the general condition improved. The improvement was, however, transitory, and the treatment was discontinued for a time. When we tried later again to inflate the pleura, adhesions had formed, produced by the treatment, and we could no longer get gas into the pleura.

To-day we should treat such a case with gold, and if by A.P.T. we should use very small amounts of gas. This was a case of acute adolescent tuberculosis. The type has been previously described by me in THE LANCET (1910, ii., 1028).

CASE 2.—A woman of 35 with gross disease in both lungs. T.B. +. Febrile. Occasional attacks of auricular fibrillation. As this case was hopeless without treatment, it could not suffer from treatment. A.P.T. attempted on the right side. Very few adhesions found. Inflation was easy. Patient bore the treatment well. Symptoms declined and there was great improvement for 18 months. Patient got up and was able to take long walks. Then relapse and death.

Autopsy showed right lung completely collapsed. A small amount of pus and oil (she had had oleothorax as well as A.P.T.) found in right chest. Left lung grossly diseased.

Large inflations of gas had been used. This was one of my early cases (1914). If I attempted to treat such a case now I should use smaller inflations, should not attempt collapse, and should rely upon oleothorax rather than A.P.T., Phrenic avulsion might also have helped. Gold never does any good in such advanced cases.

CASE 3.—A case similar to the last but with more adhesions. As the needle was pushed in and before the gas taps were opened the patient complained of feeling "queer." No inflation was attempted. The operation was at once stopped. The patient did not complain of any abnormal feeling after she went to bed, but next day it was found that she had hemiplegia, which became more pronounced during the next few days. She died within a week.

No autopsy was allowed, but this was evidently a case of embolism, probably gas embolism, though from the tardy exhibition of symptoms of paralysis it was thought we might have mobilised a thrombus. Although the gas taps were not opened the tubes contained air, and this may have been aspirated into a punctured vessel.

CASE 4.—A man of *sturdy build* and an ex-soldier. Marked lung signs. A large cavity in each upper lobe. Symptoms few. Afebrile. Patient, whilst doing light work in the sanatorium garden, had a hæmoptysis. He was sent to bed and in ten days vomited 3 pints 8 ounces of blood (measured). A.P.T. seemed *inadvisable* in view of the bilateral signs, but as death seemed inevitable it was tried on the right (the worse) lung. The treatment was successful. Hæmoptysis stopped and the patient slowly gathered strength. A.P.T. was not continued. Six months later it was decided again to try A.P.T. systematically. As the needle entered the chest, patient said "I feel queer." He became unconscious and convulsed, his cardiac rate sank to 40, and respirations quickened. Auscultation showed the presence of acute œdema; Babinski's sign was + on both sides, more marked on one side than the other. Vigorous treatment, including artificial respiration, oxygen, and pituitrin, brought him round. A week later another attempt was made, and A.P.T. was induced very easily. Great general improvement followed (patient able to get about) until the other cavity began to enlarge and he died. It seemed from the autopsy that we might have attempted to limit or suppress the cavity on the left side.

This was an extreme case of pleural reflex; although from the symptoms during the attack it was impossible a case of bilateral cortical necrosis of the kidneys which is of interest, since in Wolff's series diseases of the kidney give a low average. It will be noted that two cases of disease of the liver (acute yellow atrophy and cirrhosis) show high vitamin-A reserves, which suggests that though the diseased cell may not be capable of taking up vitamin A, it may retain much or all of that present before the onset of disease.

PUERPERAL SEPSIS AND LOW VITAMIN-A RESERVES

The present findings do not provide evidence on the question as to whether the vitamin-A reserves in puerperal sepsis are lower than in the normal puerperal woman. That they are probably lower than those of the average healthy individual appears from a comparison with the figures obtained by Moore in accident cases (Table VI.).

TABLE VI.—*Vitamin-A Content of Liver in Puerperal Women Compared with that of Normal Individual*

No. of cases.	Type of case.	b.u. per g. liver (*average*).
20	Puerperal sepsis (vitamin-A treatment).	261
13	Puerperal sepsis (no vitamin-A treatment).	122
9	Puerperal disease (non-septic).	203
23	Accidental death.	367

Since going to press data from 8 additional untreated cases have been obtained. These figures are included in Table VI. There were 4 cases of septicæmia which gave values of 10, 79, 13, 42 units per g. liver.

In the present series the average vitamin-A reserves in puerperal sepsis, even after large doses of vitamin A have been given, are seen to be definitely lower than those of presumably normal persons dying as a result of accident. Such a comparison is only suggestive, however, for on theoretical grounds it is likely that the normal liver during the puerperium is not so rich in vitamin A as it was prior to pregnancy. The fœtus must require vitamin A for its development and for building up its own reserves, the amount of which may not be insignificant, for Wolff finds an average of 73 b.u. per g. of liver in 24 new-born infants, and I have found an average of 57 units in 8 new-born infants. Wolff also finds a relatively low vitamin-A reserve in his puerperal cases (7 giving an average of 126 units). He also states that the blood of gravidæ and puerperæ is characterised by a very low amount of vitamin A in the serum.

Comparison of a larger series of septic and non-septic puerperal cases (neither group treated with vitamin A) should throw some light on the relation between low vitamin-A reserves and puerperal sepsis. Such an investigation is in progress.

Discussion

Such vitamin-A values as were found in puerperal sepsis are not in general high when compared with those of men and animals fed on good diets without special supplements of vitamin A. Under these conditions the author has found values ranging from 360 to 1100 b.u. per g. in cattle, from 110 to 700 in rabbits, and up to 14,000 in rats, whilst in man values in the region of 2000 are not uncommon. The liver reserves found under ordinary feeding conditions are far from representing the maximum capacity of the liver to store the vitamin, for in a case of pernicious anæmia in man, treated with liver, 10,500 b.u. per g. were found, whilst in a dog which had received cod-liver oil for several years the vitamin content of the liver rose to 58,000 b.u. per g.

The capacity of the liver to store vitamin A is thus far greater than its normal content on the average dietary of this country. There is at present no evidence that anything short of complete deficiency produces histological changes in the tissues. The findings of Green, Davis, Pindar, and Mellanby [6] in puerperal women do suggest, however, that though the liver may not be devoid of vitamin A the administration of extra amounts of this vitamin may increase the resistance to infection. If, as Wolff finds, the vitamin-A content of the blood is very low in puerperal women, it supports the hypothesis that a certain concentration of the vitamin in the liver is necessary before the blood can take up optimal amounts of vitamin A. A low concentration in the blood may cause weakening of some defensive mechanism against infection Observations on the blood content of vitamin A in health and disease should throw some light on this point.

Summary

1. The vitamin-A content of the liver has been determined by the antimony trichloride test in 20 cases of puerperal sepsis treated with large doses of vitamin A, and in 14 morbid puerperal cases untreated with the vitamin.

2. A large proportion of the vitamin taken by mouth was not found in the liver, and was apparently rapidly destroyed in the body.

3. Low vitamin-A reserves were found in several cases in spite of intensive treatment. In such cases septic thrombo-phlebitis was a frequent complication.

4. It is suggested that in degenerated conditions of the liver the liver cell is unable to retain the vitamin.

5. In two cases the liver was completely devoid of vitamin, according to the colorimetric test, but there were no clinical signs of vitamin-A deficiency during life.

Grateful acknowledgments are due to Dr. L. Colebrook, Dr. J. Joe, and Dr. F. Kirk for collecting the livers used in this investigation; to Prof. E. Mellanby for advice and criticism; and to Prof. L. K. Wolff and Dr. T. Moore for the privilege of seeing their results before publication.

The work was carried out with a grant from the Medical Research Council.

TWENTY YEARS' EXPERIENCE OF ARTIFICIAL PNEUMOTHORAX

BY H. DE CARLE WOODCOCK, M.D. DURH., F.R.C.P. EDIN.
CONSULTING TUBERCULOSIS OFFICER, CITY OF LEEDS

TWENTY years ago artificial pneumothorax (A.P.T.) was one of the Cinderellas of therapeutics. Even now the activities that it initiates are not clearly understood—at least not by the writer.

For years we thought it acted entirely by limiting respiratory function, putting the lung out of action as a splint stays the movement of a limb. Then it ra in too large a quantity. causing extreme ress, and danger has followed from dislocation of mediastinum. Here it is necessary to deflate at e.

pontaneous pneumothorax, not tuberculous in gin, is no uncommon occurrence. One patient, was sent to me by Dr. Durward Brown, of rrogate, whilst playing tennis felt a sudden pain in side, and X rays showed complete compression ne lung by gas. Such cases often do well without erference, but the prognosis is very different when patient has a gross tuberculous lesion. In these es deflation may be instantly called for.

ibrosis following A.P.T. affects both healthy and eased lung tissues. Pleuro-pericardial adhesions common. When disease is in both lungs and atment is attempted on both sides, the amount of used on the second side should always be limited that quantity which will limit disease activity. e's object is to stimulate sufficient but limit excess fibrosis.

OTHER CONDITIONS

When classifying the type of case's sent to hospital A.P.T., one notes the absence of patients suffering m a combined infection of joint and lung disease, ilst tubercle of the testes and of the ovary has peared quite frequently associated with cavities the lung.

N ALLERGIC SKIN REACTION AFTER SCARLET FEVER

By H. J. Gibson, M.B. Edin., D.P.H.*
LECTURER, DEPARTMENT OF BACTERIOLOGY, EDINBURGH UNIVERSITY
AND
J. P. McGibbon, M.B. Edin.
RESIDENT HOUSE PHYSICIAN, CITY HOSPITAL, EDINBURGH

The possible appearance of a condition of allergy r hypersensitiveness to the intracellular products of æmolytic streptococci has recently been suggested y a number of workers. Mackenzie and Hanger,[1] sing filtrates and nucleoprotein extracts from a umber of pathogenic organisms, including the æmolytic streptococcus, carried out intradermal ests on healthy individuals and patients suffering rom a variety of diseases. They suggested that a roportion of adults are allergic to products of one or nore organisms, but were unable to correlate the esults of the skin reactions with pre-existing infections n the subjects tested. Irvine-Jones [2] found that a high proportion of rheumatic cases gave a positive skin reaction to filtrates of four-day cultures of streptococci of all types. It should be noted that a filtrate of a culture incubated for such a period includes both diffusible exotoxin and the products of autolysis. The significance of skin reactions to a composite reagent of this nature is therefore difficult to interpret. Recently Coburn [3] has shown that patients suffering from acute rheumatism are often hypersensitive to nucleoproteins derived from the bodies of hæmolytic streptococci which have been freed from all extracellular toxic material. Collis,[4] observing a close association between throat infection with hæmolytic streptococci and cardiac relapse in children convalescent from acute rheumatism, was able to demonstrate a high degree of cutaneous hypersensitiveness to proteins of this organism in rheumatic cases.

The skin reaction which Coburn and Collis described was of the papular type, quite unlike the flat reaction of the Dick test. They have suggested that the rheumatic state results from a number of predisposing causes of which not the least important is an allergy to products liberated from foci of infection with hæmolytic streptococci.

The possibility of applying a skin test clinically to determine whether this factor is present in doubtful rheumatic cases is of special interest, and the present work was undertaken to discover whether a known streptococcal infection produced such an allergic state. Dick toxin and preparations containing the soluble intracellular products of two strains of hæmolytic streptococci have been used as reagents for carrying out intradermal tests on children suffering from scarlet fever. Each child was inoculated with the three test substances on admission to hospital and at weekly intervals throughout the illness.

METHODS

The Dick toxin used was the standard product issued by Burroughs Wellcome, Limited.

Extracts of streptococci were prepared as follows: The strains used were (1) S.S.1, a standard laboratory culture of a hæmolytic streptococcus originally isolated from a case of scarlatina and known to produce a potent Dick toxin; (2) N.S., a strain recently isolated from the throat of a child suffering from subacute rheumatism. This strain was chosen at random as being one from a non-scarlatinal source. The 24-hour growth from 100 c.cm. of phosphate broth (containing 0·2 per cent. glucose) was removed by centrifuging and washed twice in sterile normal saline. The sediment from the second washing was then transferred to a bacteriological ball-mill, dried and ground. The resulting powder, taken up in 10 c.cm. of sterile saline and centrifuged to remove bacterial debris, was the crude extract used in the tests. It is to be noted that no chemical treatment of the organisms was applied in its preparation. The dilution for skin testing was 1 : 100, which had been found by preliminary tests to be capable of producing distinct reactions without any evidence of primary toxicity such as might give "false positives."

All tests were intradermal in the volar aspect of the forearm, 0·2 c.cm. of the material being injected. Readings were made at 24, 36, and 48 hours. (The skin reactions to the bacterial extracts were found to be maximal after 36 hours.)

RESULTS

Twenty-eight cases were examined throughout the course of the disease and during convalescence. They could be divided into two groups according to the results, viz. :—

Group I (22 cases).—Those developing an allergic reaction which appeared during the second, third, or fourth week.

Group II (6 cases).—Those in which no allergic reaction was obtained or in which the reaction, if present on admission, did not show an increase after the disease.

The allergic reaction which developed was identical with that described by Mackenzie and Hanger, Coburn, and Collis.

Within 12 hours of injection of the diluted extract an area of redness appeared which increased in intensity to reach a maximum after 36 hours. The fully developed reaction consisted of a central dark red swollen area which attained in some cases a diameter of 20 mm. Surrounding this was a variable zone of erythema, paler in colour and usually clearly defined in its margin from the surrounding skin. In the stronger reactions a definite zone of pallor surrounded the whole area. In other cases this was absent and the margin faded imperceptibly into the unaffected skin. In the more marked reactions the centre of the inner œdematous zone was pale and almost necrotic in appearance, though the skin never broke down. Slight pain was occasioned on movement of the arm, and tenderness was a feature of all moderate and severe reactions. Fading was rapid after 36–48 hours, the peripheral zone disappearing

---

* In receipt of a part-time grant from the Medical Research Council.

to exclude gas embolism, it should be noted that there was no subsequent paralysis.

CASE 5.—Similar physical signs to above. The right lung grossly affected, the left lung slightly affected. At the consultation we decided to attack the left lung because the disease in the left lung seemed active. A.P.T. was induced on the left. A fatal hæmoptysis occurred two days later, and we judged that this came from the more grossly diseased lung, and we also thought that interference with the left lung had caused the catastrophe in the right.

CASE 6.—A flying officer with apparently unilateral disease had a history of recurrent hæmoptysis. A large inflation produced considerable dyspnœa and cyanosis. All this quietened down and the patient seemed in good condition and ready in a week for another inflation. In principle the patient agreed to the repetition but delayed the act. In five weeks, a day before the A.P.T. was to be repeated, the patient had a fatal hæmoptysis.

CASE 7.—The patient had been known to me as one suffering from pulmonary tuberculosis for many years. A rather sudden onset of acute broncho-pneumonia sent him into hospital. He seemed in a most critical condition. High febrility. Rapid pulse. Some but not extreme dyspnœa. Slight cyanosis. Sputum excessive. Disease bilateral. T.B. + +. A.P.T. was induced in the worse lung with remarkable success. Patient was walking about in a month's time. This was in 1914, soon after I had introduced oleothorax to the profession as a new method of treatment. Oleothorax was used as well as A.P.T., a pint of oil being injected into the pleura.

The case was published in the *Edinburgh Medical Journal* (November, 1915), where fuller details are to be found. The patient died some years later from hæmoptysis.

CASE 8.—An army officer with a history of chronic pulmonary tuberculosis had an acute attack of broncho-pneumonia, somewhat similar to the last-mentioned case. He was treated in the same way and with the same success. Then an interlobar empyema developed and was treated by aspiration and oleothorax. Patient gained several stones in weight and was able to carry on an exacting employment, his main trouble being dyspnœa on exertion. He was subject to relapses, always associated with broncho-pneumonia, generally relieved by deep aspiration of pus. The question of phrenic avulsion and thoracoplasty was raised, and eventually phrenic avulsion was adopted with considerable success.

One can never tell when one has finished with such a case, and the fear of hæmoptysis is ever present.

CASE 9.—Very similar to the above. This patient, a man in easy circumstances, was treated by A.P.T. in 1913. Eighteen inductions were carried out. For ten years he remained in comparatively good health and able to manage his business. Then hæmoptysis. The disease was then in a fibrotic stage with dense adhesions on the left (the worse) side. A.P.T. and oleothorax carried out with difficulty owing to adhesions. Thoracoplasty advised by Dr. Vera Pearson, to whom I sent him. The patient, however, began to improve again, and I negatived thoracoplasty and advised phrenic avulsion. The patient was against additional procedure as he felt comparatively well. Acute fatal hæmoptysis occurred 15 years after the commencement of treatment.

CASE 10.—A patient, 16 years of age, with chronic bronchiectasis and massive fibrosis almost confined to the left lung. Very ill—sub-febrile, emaciated. Sputum very offensive. Hæmoptysis not great but recurrent. Thoracoplasty advised but rejected. A.P.T. and oleothorax attempted, and although there were many adhesions and complete compression was of course out of the question, several considerable inflations, followed by injections of oil in large quantities, produced a very remarkable result. Patient was kept under close observation and was subjected to small inflations about every three months. The treatment was then empirical rather than logical. The patient is now able to work; I am certain there is a danger of relapse.

Since this paper was written the relapse has come.

CASES 11 and 12.—Two similar cases, middle-aged men, with chronic fibrosis and bronchitis, sputum excessive. Basal bronchiectasis, chiefly on one side. T.B. were found in one, but not in the other.

Treated with oleothorax with great temporary benefit. (I always give A.P.T. first before injecting the oil.) Oleothorax most valuable in such chronic cases after A.P.T. has done its partial compression. (See report of International Congress of Medicine, 1913, in which oleothorax was suggested and two cases described—the first, I think, in modern medicine.) I think it is of value as an alternative to the more drastic thoracoplasty. In one patient acute pulmonary œdema followed the introducing of the needle and frightened me into not attempting further treatment, but in most cases the patient bears the treatment well.

Dr. N. Tattersall has recently told me of a case in which a successful pneumothorax was gradually becoming obliterated by pleural creep. He filled up the pleural cavity with gomenolised oil (1½ pints), and the patient remained in excellent health for 18 months. She then developed pneumonia, followed by an empyema on the treated side, which ruptured into the lung, and pus and oil were being coughed up before the presence of the empyema had been suspected. All the pus and oil have now been aspirated, and the case is improving on pleural lavage with 1 in 2000 acriflavine. Thoracoplasty will probably be required in this case to close the cavity, as the lung is tightly bound down by thick visceral pleura.

CASE 13.—Patient with acute lobar pneumonia which began in hospital where he was being treated with A.P.T. The A.P.T. was discontinued as it increased the dyspnœa and cyanosis.

CASE 14.—Patient with acute lobar pneumonia with hæmoptysis and T.B. negative. A.P.T. was done to check the considerable amount of bleeding. The treatment stopped the hæmoptysis and aborted the pneumonia. After the induction the patient, feeling comparatively well, went home. Relapse; death from pneumonia.

CASE 15.—A patient whose case was diagnosed by his doctor as one of pneumonic phthisis with T.B. in sputum, was removed by me to hospital and treated with A.P.T.

This was a case of acute lobar pneumonia, and I recognised that I had made a mistake in diagnosis. The T.B. in the sputum must have been from a small lesion and was independent of the acute illness from which the patient had suffered.

Several French writers have been impressed by the occurrence of broncho-pneumonia, together with tubercle, in patients admitted to hospital. They have found that rest in bed is generally the best method of treatment. I have read with great interest the cases of acute lobar pneumonia treated by A.P.T. (J. J. Coghlan, THE LANCET, 1932, i., 13).

CASE 16.—A patient, apparently suffering from unilateral pulmonary tuberculosis, was treated by A.P.T. Whilst undergoing treatment she began to have diarrhœa which could not be permanently arrested, though Dr. A. F. Hurst's extreme acid treatment was tried. The question arose whether or no the A.P.T. had stimulated the intestinal disease, hitherto latent. This gastro-intestinal disturbance, whether produced by treatment or independent of treatment, is a great bar to further treatment by A.P.T. In one case, a non-tuberculous abscess of the lung, persistent and distressing vomiting for some time followed a few inductions.

FIBROSIS

All our methods of treatment induce fibrosis, and this of course has its attendant dangers. Patients with fibrosis and intermittent dyspnœa, generally spoken of under the heading of asthma, should be left alone unless other conditions demand treatment. A.P.T., by inducing pulmonary œdema, may precipitate an "asthmatic attack." I have seen fibrosis in the lung apparently induce a similar condition outside the lung. In one case there was stiffness of the muscles of the neck simulating spinal disease, though careful examination and observation (X ray included) did not indicate any bone disease. Marked emphysema is always a contra-indication to A.P.T., especially in the middle-aged patient. I have seen many examples where the gas has been introduced into the naphylaxis. An anaphylactic state associated with rculating antibodies and passively transferable to nother animal may be induced by injection of acterial proteins, as with almost any other protein, ut this state is not comparable with the allergy esulting from infection with the same organism. hese observers have contrasted the hypersensitiveness ollowing "injection" with that resulting from "infection."

Dochez and Stevens,[7] in work on the induction of a "Dick-positive" state in animals, showed that two phases could be demonstrated. In the early stages of sensitisation, filtrates of hæmolytic streptococci produced a "flat" type of erythematous reaction, and this effect could be readily neutralised with a specific antiserum. No reaction followed injection of heated filtrate at this stage. Later the reaction was papular in type and no neutralisation with any serum was possible while the reacting substance in the filtrate was thermostable. It was also noted that the late papular type of reaction was less specific than the early one, equally good results being obtained with strains of hæmolytic streptococci from sources other than scarlet fever. In scarlet fever the Dick reaction has been thought to correspond with the first phase. The present work shows that while both the "Dick-positive" phase and the allergic phase are found at different times in the course of scarlet fever, the reagents necessary to elicit the reactions differ. The early flat reaction is produced by the diffusible products of the organism, as found in filtrates of young fluid cultures, while the later papular lesion is a response to material from the bacterial bodies freed from extracellular toxins.

The clinical significance of the development of this highly allergic state in the late stages of scarlet fever is difficult to assess. The products of the organism are apparently toxic to the skin of such an individual, in the same way as tuberculin is toxic to a tuberculous person. If, therefore, a persistent focus of infection were present in the throat in the later stages, reactive products might be liberated into the blood stream and produce late toxic effects. It may be that this process is concerned in the production of rheumatism and nephritis complicating scarlet fever, since these conditions frequently appear after the early toxic phase, as manifested by fever and rash, has subsided.

The results reported here have no direct bearing on the ætiology of acute rheumatism. Of many who acquire the specific hypersensitiveness as a result of scarlatina, few subsequently show evidence of the rheumatic syndrome. All that can be said in this connexion is that the papular reaction of allergic type following intradermal injection of products of a hæmolytic streptococcus cannot be regarded as specific for acute rheumatism. The question of the persistence of the allergic state is of obvious importance and requires further investigation.

SUMMARY

1. In a series of cases of scarlet fever weekly intracutaneous tests have been carried out with an extract prepared from cultures of hæmolytic streptococci representing the soluble intracellular products of the organisms freed from diffusible substances. The extract was diluted 1 : 100 for the test.

2. Twenty-eight cases were examined and in 22 the reaction, negative during the first week, developed and became strongly positive by the fourth week.

3. All cases over 7 years of age acquired the allergic reaction.

4. The possible fallacy, that the reaction noted in convalescence is simply a recrudescence of a pre-existing skin-sensitiveness temporarily inhibited during the fever, is discussed.

We wish to acknowledge the kindness of Dr. W. T. Benson in giving us access to his cases. We are also indebted to Prof. T. J. Mackie for his advice and help throughout the work.

AN AID IN THE TREATMENT OF TOXÆMIA OF PREGNANCY

BY SAMUEL J. CAMERON, M.B., F.R.F.P.S. GLASG., F.C.O.G.

CONSULTING OBSTETRIC SURGEON TO THE COUNTY OF LANARK MATERNITY HOSPITAL, BELLSHILL

DURING 1929 over 600 women in Great Britain died from eclampsia, and it is therefore probable that each year several thousand—who have had toxæmia without reaching a convulsive stage—suffer from prolonged ill-health, or are doomed to premature death, in consequence of the damage sustained by the kidneys with or without hepatic involvement. Dr. H. Thomson and myself, from observations made at the County of Lanark Hospital, Bellshill, and at the Royal Maternity Hospital, Glasgow, are convinced that this need no longer be so if the simple line of treatment recommended by us be adopted.

We are of opinion that calcium is the main custodian of hepatic efficiency during pregnancy, and also that the calcium content of the blood is low at that time and especially during the pre-eclamptic state. We also believe that there is an accompanying deficiency of alkali. Hence, for over a year and a half all cases of albuminuria of pregnancy in the outdoor and indoor departments of the Maternity Hospital at Bellshill have been treated with calcium, potassium citrate, and sodium bicarbonate, and the results have been so favourable that we consider a great advance has been made.

A. A. Osman and H. G. Close [1] in 1931 demonstrated in normal pregnancy that there is a decrease in the plasma bicarbonate, and that this state persists throughout gestation. On the other hand the water content of the blood and tissues is increased and becomes greater as the plasma bicarbonate diminishes. By treating cases of albuminuria of pregnancy with alkalis they found that the amount of albumin in the urine became less, although the œdema occasionally increased after the initial dose. Potassium citrate and sodium bicarbonate, grs. 50 of each, were given in 1½ oz. of water several times a day and the fluid was restricted to 4 pints in the 24 hours. Each day the dosage was increased. The patients were kept in bed and a full diet was allowed.

We are strongly of opinion that such cases should be treated with calcium as well as alkalis, and also that the maximum effect of the calcium is obtained within 12 hours, though traces of the inner papular lesion remained for some days. The allergic reaction thus differed from the Dick reaction in its rather later development after injection and in the presence of the swollen and tender dark red central area.

---

[1] Proc. Roy. Soc. Med., 1931, xxiv. (Sect. Obst. and Gyn.), 49.

The group of cases developing such an allergic reaction could be subdivided by reference to the results of the Dick test (see Table I.). In 14 cases the Dick reaction showed the usual change from positive to negative. In 6 cases the initial Dick test was negative, though the clinical condition on admission and the subsequent course of the disease showed it to be true scarlet fever. In 2 cases the Dick test remained positive throughout. Table II. illustrates the actual readings made on a case in the group showing an initial positive Dick reaction with the late development of a reaction to the bacterial extract. The difference in degree of reaction with strain S.S.1 and strain N.S. respectively was noted throughout. The strain S.S.1 was the scarlatinal strain which had been maintained in culture for many years. When a freshly isolated scarlatinal strain (S.2) was substituted for S.S.1 the reactions were exactly equal to those obtained with strain N.S. (see Table III.). It may be that the hæmolytic streptococcus loses to some extent the reacting principle after prolonged artificial culture.

TABLE I

Twenty-two cases of scarlet fever showing development of allergy to streptococcus extract, grouped according to results of Dick tests.

Dick test.		Allergic reaction.		Cases.
On admission.	On discharge.	On admission.	On discharge.	
Positive.	Negative.	Negative.	Positive.	14
Negative.	,,	,,	,,	6
Positive.	Positive.	,,	,,	2

TABLE II

Example of results obtained in skin tests on an adult, aged 24, during scarlet fever.

Reagent used in skin test.	Weeks—			
	First.	Second.	Third.	Fourth.
Dick toxin	24 × 18	Nil.	Nil.	Nil.
"Dick control" ..	Nil.	,,	,,	,,

Cases not developing an allergic reaction.—These cases numbered 6 of the 28 investigated. In 1 the reaction to streptococcus extracts was negative throughout. In the other 5 cases a faint rash was noted during the first week, and this persisted throughout, with no tendency to increase.

Influence of age on the reaction.—The number of cases examined is too small to provide adequate data from which to draw any conclusions as to the influence of age in the development of the allergic reaction. The ages varied from 1½ years to 24 years. It is noteworthy that all cases over the age of 7 years developed marked allergy. These numbered 13. Of the 15 cases of 7 years and under, 9 developed the allergic reaction and 6 did not.

This finding is of interest, since Mackenzie and Hanger [1] showed that in unselected normal children and adults the proportion of reactors to bacterial extracts of various bacteria increased with age, as also did the severity of the lesions produced. It is very uncommon to meet with a pseudo-reaction in the Schick test during childhood, but towards adolescence these reactions become more frequent. This is probably another example of the same phenomenon.

DISCUSSION

It appears from these results that in a proportion of cases infection with the hæmolytic streptococcus is capable of producing a condition of hypersensitiveness to intracellular products of this organism. This finding would bring streptococcal disease into line with a number of infections known to result in allergy to the specific antigen.

It might be objected, however, that these reactions were a manifestation of a pre-existing allergic state suppressed during the febrile stage of the illness and reappearing in convalescence. It must, of course, be noted that a similar reaction can be elicited in apparently normal persons who have not previously suffered from a recognisable streptococcal infection. Such reactions, however, occur in a minority of urban children during the age-period 6–15 years. This had been shown by Coburn in New York, Collis in London, and H. J. Gibson and D. Stewart (unpublished observations) in Edinburgh, where 35 per cent. of normal children have been found to react. The disappearance of such allergic reactions during periods of fever or extreme weakness from any cause has been reported by certain observers, this inhibition being quite non-specific (see Mackenzie and Hanger [1]).

The fact that in our work 75 per cent. of the cases and all over the age of 7 became hypersensitive in convalescence suggests that the positive skin reactions were directly due to the infection and did not result merely from a recrudescence of a temporarily suppressed reactive state. It should be noted that all cases with sharp pyrexia or evidence of marked toxæmia were excluded from our series owing to the routine administration of antitoxin. Thus only mild cases were investigated. It does not seem probable that such cases with only slight and transient systemic disturbance would lose their skin reactivity. Finally, as showing that fever does not necessarily inhibit the reaction, may be mentioned a case of scarlatinal arthritis in the third week of the disease with a temperature of 101·6° F. in which a lesion of diameter 75 × 35 mm. was produced. The evidence seems to suggest that the allergic condition, as shown by the cutaneous reaction during convalescence, had arisen de novo and had not existed in the patients before the disease commenced.

We do not propose to discuss at length the mechanism of these reactions. The work of Zinsser and his co-workers [5] [6] has shown that this "allergy of infection" is fundamentally different from re than a superficial one (cf. Case 2). The abscess y extend up behind the soft palate, and down as as the post-laryngeal region. It may coexist th a cervical swelling—i.e., apparent cervical enitis. Hence, where an adenitis is present in the per cervical region, the retropharyngeal region ould be examined for any signs of an abscess there ase 1).

The diagnosis is completed by palpation. The oistened finger is gently inserted into the pharynx d the swelling palpated. Fluctuation may be tected bimanually with any coexisting mass in e neck. The mass may be hard and yet pus be resent. In such a case it is prudent to aspirate the tropharyngeal swelling through the mouth with a ick-bore needle and syringe. In adults, a cocaine nd adrenaline spray to the throat is sufficient næsthetic. The hawking produced by introducing he needle into the tumour will often force pus into he syringe, without the aid of suction (Case 4). ccasionally a diagnosis of retropharyngeal abscess nay be made in infants with the direct laryngoscope Case 6). When persistent inflammatory signs and ymptoms occur after operation for tonsils and denoids, a retropharyngeal abscess must be borne n mind as a possible complication (Case 3).

ANTERIOR AND POSTERIOR QUINSY

Just as pus, collecting between the tonsil capsule and the anterior pillar, produces a quinsy—i.e., an anterior quinsy, which pushes the tonsil posteriorly—so pus may form towards the posterior aspect of the tonsil, pushing it forwards and producing a "posterior" quinsy. This collection is between the mucous membrane of the posterior pillar and that of the posterior pharyngeal wall, and inside the pharyngeal fibrous layer. It simulates a retropharyngeal abscess but is not so deeply situated and, of course, does not extend laterally into the cervical fascial planes. Case 5 is an example of confusion in diagnosis. Only when the pus is absolutely submucous, as detected on exploration, can the diagnosis of a posterior quinsy be made with certainty.

DRAINAGE OF AN ABSCESS

In big children or adults a general anæsthetic is advisable. Young children and infants require no anæsthetic. The child is immobilised by wrapping it in a blanket which pinions the arms to the side. The head is held by an assistant and extended over a sandbag under the shoulders. The Davis tonsil gag is introduced. The surgeon, using a head-lamp, is seated at the head of the table. A moistened captive gauze swab is packed into the nasopharynx. The mucous membrane is incised by making a longitudinal tear, with the points of a closed, long, single-toothed dissecting forceps, over the most prominent part of the swelling, just medial to the posterior pillar and (usually) half-way between the soft palate and the base of the tongue, in the operative field. The initial tear is about half an inch long. It is deepened by successive strokes until a dense whitish capsule, resembling the capsule of the tonsil, comes into view. This layer must be penetrated before pus is liberated. It is the fibrous investment of the pharynx surrounding its musculature.

A retropharyngeal abscess may arise ab initio in the retropharyngeal space and remain localised there without any external cervical manifestation of its presence (Case 2); or it may extend laterally to appear as a swelling at the angle of the jaw, under cover of the sternomastoid; or it may commence as a cervical adenitis and then extend medially behind the pharynx to appear there as a retropharyngeal abscess, in which case the collection may be adequately drained through a retropharyngeal incision (Case 1). The extension passes deep to the carotid sheath, and the points of the forceps may be plunged posterolaterally without endangering the vessels. The inexperienced may be hesitant about penetrating further, as the white capsule may be at some depth from the surface. In any case of real doubt the swelling should be aspirated with the needle and syringe, when the withdrawal of pus will embolden the operator to proceed with the exposure of the abscess. Pus is liberated as soon as this "capsular" stratum is traversed. The use of an automatic sucker is advised, if one is available. In any case, the pus is mopped away, and the original opening is made as long as possible by running the points of the forceps up and down so as to tear open the tissues covering the abscess in its entire length. This may extend from well above the soft palate to the arytenoids. A gloved finger is introduced into the abscess cavity to determine its extent, and a bimanual examination is made with a finger over the neck. Pressure on any cervical mass will empty its part of the abscess into the wound. No bare bone is palpable, and the finger will break down any adhesions or loculi in the cavity.

The liberated pus, often considerable in amount, is prevented from entering the trachea by the posture and the use of the Davis gag; and it is prevented from entering the nasopharynx by the preliminary plug in the post-nasal space. The bleeding usually ceases rapidly. The cavity and throat are mopped dry, the plug is removed, and the patient is put to bed, lying on the face as after a tonsil and adenoid operation. With this wide exposure, pocketing of pus is prevented and a second operation obviated.

CASE 1. *Retropharyngeal abscess, with swelling in the neck, receding on retropharyngeal drainage.*—A child, aged 6, had tonsillitis with cervical adenitis. The illness commenced with a temperature and epistaxis, for which no cause was obvious. The pyrexia persisted, and on the tenth day the adenitis was still present. The glands were hard, and no trace of fluctuation or softening could be detected. There was now visible a painless fullness behind the right posterior pillar, detectable as a vertical band. Under anæsthesia, as described above, the retropharyngeal mass was explored with forceps. The pus was evacuated and the prominent cervical swelling collapsed completely. An external incision was avoided, a point of some importance when the patient is a girl. A month later there was no trace of cervical adenitis. The throat was normal and the tonsils small.

CASE 2. *Retropharyngeal abscess, simulating an acute aural condition.*—A girl, aged 9, whose tonsils had been removed by me three years before, had an acute febrile illness, with a temperature up to 104° and with mild bilateral cervical adenitis at the angle of the jaw. The swellings subsided, but there was severe pain in the left ear and dysphagia. A rigor occurred. I saw the child on the third day of the ear symptoms. There was tenderness over the mastoid, exquisite at the angle of the jaw. There was no cervical swelling. The tympanic membrane was normal. Behind the posterior pillar was a red swelling, tender to palpation, pushing it forwards to form a bulge behind it. The abscess subsequently burst. It resembled an inflamed tonsil, inasmuch as it formed a bulge behind the pillar. As the anterior pillar had atrophied after the tonsillectomy, the simulation of a tonsil was complete. The severe pain referred to the ear, the mastoid tenderness, and the rigor, coupled with a long, swinging temperature, gave rise to the suspicion of an acute aural condition.

CASE 3. *Retropharyngeal abscess, a complication of the operation for tonsil and adenoids.*—Two weeks after guillotining of tonsils, a child was admitted pale and ill, with a temperature of 103°, a rigid neck, and slight adenitis on one side. Mucopus welled out from the post-nasal space. No foreign body—e.g., a retained swab—was present. For the next week the temperature remained raised; then the source of the pus was traced to a leaking centrally situated when given in combination with the alkalis. At the *Maternity Hospital, Bellshill, over 400 cases* of albuminuria of pregnancy have been treated in the indoor and dispensary departments since the closing months of 1930 with a mixture of calcium sodium lactate (grs. 7½), potassium citrate (grs. 40), and sodium bicarbonate (grs. 20). For ease of administration these medicaments are prepared by Parke, Davis and Co. for us in tablet form with a flavouring agent, and three or four tablets a day are prescribed. These tablets are very soluble. It is interesting to observe the fall which has taken place in the number of cases of eclampsia admitted to this hospital since this special treatment was instituted.

Year.	Cases.	Year.	Cases.
1926	27	1930	38
1927	19	1931	8
1928	24	1932	7
1929	22		

It is important to note that this treatment was started towards the close of 1930, and that all the cases admitted during 1931 and a part of 1932 had never been to one of the antenatal centres and had not received the special treatment. Therefore the women who were under treatment by calcium and the alkalis were immune to this complication of pregnancy. The treatment cannot be expected to cure cases which are suffering from a chronic renal lesion, for the kidney is already permanently damaged and lacks the pronounced permeability of the kidney during normal pregnancy or the pre-eclamptic state. For this reason this special treatment is contra-indicated in cases of chronic renal disease, since alkalosis may supervene, but we imagine that this risk has been exaggerated. In the pre-eclamptic state with abundant albumin in the urine we always administer the drugs intravenously as soon as the case comes under observation. For this purpose the sterile solution of calcium gluconate (Sandoz) is used by us. Each ampoule contains 10 c.cm. of the solution, and the contents of one ampoule is mixed with sterilised potassium citrate and sodium bicarbonate in about a pint of boiled water.

A sterile solution of potassium citrate and potassium bicarbonate can be obtained in ampoules from some of the large chemical manufacturers, and in hospital we keep the calcium and alkali solutions in separate ampoules so that pre-eclamptic cases can receive immediate treatment. Apparently potassium bicarbonate can be rendered sterile by repeatedly heating it to a temperature of 150° F. without disintegrating, but when we made our own preparations we mixed the calcium and alkaline solutions in the cold state before bringing them to blood heat for intravenous injection. We consider that by so doing the various ingredients are more likely to retain their individuality, although from a practical point of view this may be relatively unimportant as probably all that is necessary is to provide an alkaline medium wherein the calcium can exercise its function to the best advantage. Sometimes we inject the alkalis first and later the sterile calcium solution. The effect of intravenous medication in many instances is dramatic, and quotation of a case treated by us will serve as an example of what may occur.

A primigravida was admitted with œdema so extreme that the eyes were practically hidden, there was severe headache, and high blood pressure. The output of urine was small and it boiled so solid that in order to estimate the albumin present the urine had to be diluted. The reading was then found to be 17, and after intravenous injection it dropped in 24 hours to 6 and on the following day to 0·5. The œdema rapidly disappeared, the blood pressure fell, and the quantity of urine secreted quickly increased, and within a few days the patient, who was admitted in a pronounced state of toxæmia, was happy and *comfortable.*

After injection four tablets a day are taken orally by the patient, but the intravenous administration should be repeated if the albumin begins to increase in amount and the blood pressure rises. A temporary but pronounced improvement may be expected, but if any anxiety exists labour should be induced, and this can be done with comparative safety as the patient is no longer being overwhelmed by the murky waters of the pre-eclamptic state. If the calcium and alkali treatment were omitted many of these patients would probably develop convulsions during induction of labour.

The public health authorities of Glasgow and the County of Lanark are now using this form of treatment in all their antenatal centres and we advise that the administration of these drugs should be *started about the fourth month of pregnancy.* Not only may toxæmia be thus prevented, but the alkalinity of the urine which is produced may have an inhibitory influence on the activities of the *Bacillus coli communis* and diminish the incidence of pyelitis. Recently it has come to my knowledge that one of my colleagues at the Western Infirmary, Glasgow (Dr. J. A. W. McCluskie), always gives intravenous injection of calcium before using salvarsan in cases of syphilis, for as he finds it is a reliable preventive of acute yellow atrophy of the liver—a complication which is liable to arise if salvarsan alone be used. This circumstance is additional confirmation of the protective action of calcium in connexion with hepatic metabolism. We have obtained less satisfactory results in the pre-eclamptic state from the intramuscular injection of calcium and consequently we recommend intravenous administration.

SOME POINTS IN THE DIAGNOSIS AND TREATMENT OF THE
ACUTE RETROPHARYNGEAL ABSCESS

By N. Asherson, M.B., B.S. Lond., F.R.C.S. Eng.

ASSISTANT SURGEON TO THE CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL; SURGEON FOR DISEASES OF THE EAR NOSE, AND THROAT TO THE QUEEN'S HOSPITAL FOR CHILDREN

An acute retropharyngeal abscess presents behind the posterior pharyngeal wall, medial and posterior to the posterior faucial pillar, in the potential space between the prevertebral fascia and the fascia investing the pharynx. This chink extends laterally behind the carotid sheath and passes under the sternomastoid muscle towards its posterior border. It contains loose tissue which enables the pharyngeal wall to be raised easily and to a great extent away from the posterior vertebral support by any collection of pus.

For examination of the throat the patient faces directly forwards. If the head is deviated to one side, the transverse process of the upper cervical vertebra forms a prominence behind the posterior pillar, and so simulates a retropharyngeal abscess. This prominence may be very striking.

The abscess may thrust forward the posterior pillar and, where the tonsils have been previously removed, this bulge may simulate an inflamed tonsil. As the anterior faucial pillar invariably atrophies after tonsillectomy, the bulge described is, to the non-discriminating observer, behind a pillar (mistaken for the anterior pillar) and the resemblance may be re than a superficial one (cf. Case 2). The abscess y extend up behind the soft palate, and down as as the post-laryngeal region. It may coexist th a cervical swelling—i.e., apparent cervical enitis. Hence, where an adenitis is present in the per cervical region, the retropharyngeal region ould be examined for any signs of an abscess there ase 1).

The diagnosis is completed by palpation. The oistened finger is gently inserted into the pharynx d the swelling palpated. Fluctuation may be tected bimanually with any coexisting mass in e neck. The mass may be hard and yet pus be resent. In such a case it is prudent to aspirate the tropharyngeal swelling through the mouth with a ick-bore needle and syringe. In adults, a cocaine nd adrenaline spray to the throat is sufficient næsthetic. The hawking produced by introducing he needle into the tumour will often force pus into he syringe, without the aid of suction (Case 4). ccasionally a diagnosis of retropharyngeal abscess nay be made in infants with the direct laryngoscope Case 6). When persistent inflammatory signs and ymptoms occur after operation for tonsils and denoids, a *retropharyngeal* abscess must be borne n mind as a possible complication (Case 3).

ANTERIOR AND POSTERIOR QUINSY

Just as pus, collecting between the tonsil capsule and the anterior pillar, produces a quinsy—i.e., an anterior quinsy, which pushes the tonsil posteriorly—so pus may form towards the posterior aspect of the tonsil, pushing it forwards and producing a "posterior" quinsy. This collection is between the mucous membrane of the posterior pillar and that of the posterior pharyngeal wall, and inside the pharyngeal fibrous layer. It simulates a retropharyngeal abscess but is not so deeply situated and, of course, does not extend laterally into the cervical fascial planes. Case 5 is an example of confusion in diagnosis. Only when the pus is absolutely submucous, as detected on exploration, can the diagnosis of a posterior quinsy be made with certainty.

DRAINAGE OF AN ABSCESS

In big children or adults a general anæsthetic is advisable. Young children and infants require no anæsthetic. The child is immobilised by wrapping it in a blanket which pinions the arms to the side. The head is held by an assistant and extended over a sandbag under the shoulders. The Davis tonsil gag is introduced. The surgeon, using a head-lamp, is seated at the head of the table. A moistened captive gauze swab is packed into the nasopharynx. The mucous membrane is incised by making a longitudinal tear, with the points of a closed, long, single-toothed dissecting forceps, over the most prominent part of the swelling, just medial to the posterior pillar and (usually) half-way between the soft palate and the base of the tongue, in the operative field. The initial tear is about half an inch long. It is deepened by successive strokes until a dense whitish capsule, resembling the capsule of the tonsil, comes into view. This layer must be penetrated before pus is liberated. It is the fibrous investment of the pharynx surrounding its musculature.

A retropharyngeal abscess may arise ab initio in the retropharyngeal space and remain localised there without any external cervical manifestation of its presence (Case 2); or it may extend laterally to appear as a swelling at the angle of the jaw, under cover of the sternomastoid; or it may commence as a cervical adenitis and then extend medially behind the pharynx to appear there as a retropharyngeal abscess, in which case the collection may be adequately drained through a retropharyngeal incision (Case 1). The extension passes deep to the carotid sheath, and the points of the forceps may be plunged posterolaterally without endangering the vessels. The inexperienced may be hesitant about penetrating further, as the white capsule may be at some depth from the surface. In any case of real doubt the swelling should be aspirated with the needle and syringe, when the withdrawal of pus will embolden the operator to proceed with the exposure of the abscess. Pus is liberated as soon as this "capsular" stratum is traversed. The use of an automatic sucker is advised, if one is available. In any case, the pus is mopped away, and the original opening is made as long as possible by running the points of the forceps up and down so as to tear open the tissues covering the abscess in its entire length. This may extend from well above the soft palate to the arytenoids. A gloved finger is introduced into the abscess cavity to determine its extent, and a bimanual examination is made with a finger over the neck. Pressure on any cervical mass will empty its part of the abscess into the wound. No bare bone is palpable, and the finger will break down any adhesions or loculi in the cavity.

The liberated pus, often considerable in amount, is prevented from entering the trachea by the posture and the use of the Davis gag; and it is prevented from entering the nasopharynx by the preliminary plug in the post-nasal space. The bleeding usually ceases rapidly. The cavity and throat are mopped dry, the plug is removed, and the patient is put to bed, lying on the face as after a tonsil and adenoid operation. With this wide exposure, pocketing of pus is prevented and a second operation obviated.

CASE 1. *Retropharyngeal abscess, with swelling in the neck, receding on retropharyngeal drainage.*—A child, aged 6, had tonsillitis with cervical adenitis. The illness commenced with a temperature and epistaxis, for which no cause was obvious. The pyrexia persisted, and on the tenth day the adenitis was still present. The glands were hard, and no trace of fluctuation or softening could be detected. There was now visible a painless fullness behind the right posterior pillar, detectable as a vertical band. Under anæsthesia, as described above, the retropharyngeal mass was explored with forceps. The pus was evacuated and the prominent cervical swelling collapsed completely. An external incision was avoided, a point of some importance when the patient is a girl. A month later there was no trace of cervical adenitis. The throat was normal and the tonsils small.

CASE 2. *Retropharyngeal abscess, simulating an acute aural condition.*—A girl, aged 9, whose tonsils had been removed by me three years before, had an acute febrile illness, with a temperature up to 104° and with mild bilateral cervical adenitis at the angle of the jaw. The swellings subsided, but there was severe pain in the left ear and dysphagia. A rigor occurred. I saw the child on the third day of the ear symptoms. There was tenderness over the mastoid, exquisite at the angle of the jaw. There was no cervical swelling. The tympanic membrane was normal. Behind the posterior pillar was a red swelling, tender to palpation, pushing it forwards to form a bulge behind it. The abscess subsequently burst. It resembled an inflamed tonsil, inasmuch as it formed a bulge behind the pillar. As the anterior pillar had atrophied after the tonsillectomy, the simulation of a tonsil was complete. The severe pain referred to the ear, the mastoid tenderness, and the rigor, coupled with a long, swinging temperature, gave rise to the suspicion of an acute aural condition.

CASE 3. *Retropharyngeal abscess, a complication of the operation for tonsil and adenoids.*—Two weeks after guillotining of tonsils, a child was admitted pale and ill, with a temperature of 103°, a rigid neck, and slight adenitis on one side. Mucopus welled out from the post-nasal space. No foreign body—e.g., a retained swab—was present. For the next week the temperature remained raised; then the source of the pus was traced to a leaking centrally situated when given in combination with the alkalis. At the Maternity Hospital, Bellshill, over 400 cases of albuminuria of pregnancy have been treated in the indoor and dispensary departments since the closing months of 1930 with a mixture of calcium sodium lactate (grs. 7½), potassium citrate (grs. 40), and sodium bicarbonate (grs. 20). For ease of administration these medicaments are prepared by Parke, Davis and Co. for us in tablet form with a flavouring agent, and three or four tablets a day are prescribed. These tablets are very soluble. It is interesting to observe the fall which has taken place in the number of cases of eclampsia admitted to this hospital since this special treatment was instituted.

Year.	Cases.	Year.	Cases.
1926 ……	27	1930 ……	38
1927 ……	19	1931 ……	8
1928 ……	24	1932 ……	7
1929 ……	22		

It is important to note that this treatment was started towards the close of 1930, and that all the cases admitted during 1931 and a part of 1932 had never been to one of the antenatal centres and had not received the special treatment. Therefore the women who were under treatment by calcium and the alkalis were immune to this complication of pregnancy. The treatment cannot be expected to cure cases which are suffering from a chronic renal lesion, for the kidney is already permanently damaged and lacks the pronounced permeability of the kidney during normal pregnancy or the pre-eclamptic state. For this reason this special treatment is contra-indicated in cases of chronic renal disease, since alkalosis may supervene, but we imagine that this risk has been exaggerated. In the pre-eclamptic state with abundant albumin in the urine we always *administer the drugs intravenously as soon as the* case comes under observation. For this purpose the sterile solution of calcium gluconate (Sandoz) is used by us. Each ampoule contains 10 c.cm. of the solution, and the contents of one ampoule is mixed with sterilised potassium citrate and sodium bicarbonate in about a pint of boiled water.

A sterile solution of potassium citrate and potassium bicarbonate can be obtained in ampoules from some of the large chemical manufacturers, *and in hospital* we keep the calcium and alkali solutions in separate ampoules so that pre-eclamptic cases can receive immediate treatment. Apparently potassium bicarbonate can be rendered sterile by repeatedly heating it to a temperature of 150° F. without disintegrating, but when we made our own preparations we mixed the calcium and alkaline solutions in the cold state before bringing them to blood heat for intravenous injection. *We consider that by so doing the various* ingredients are more likely to retain their individuality, although from a practical point of view this may be relatively unimportant as probably all that is necessary is to provide an alkaline medium wherein the calcium can exercise its function to the best advantage. Sometimes we inject the alkalis first and later the sterile calcium solution. The effect of intravenous medication in many instances is dramatic, and quotation of a case treated by us will serve as an example of what may occur.

A primigravida was admitted with œdema so extreme that the eyes were practically hidden, there was severe headache, and high blood pressure. The output of urine was small and it boiled so solid that in order to estimate the albumin present the urine had to be diluted. The reading was then found to be 17, and after intravenous injection it dropped in 24 hours to 6 and on the following day to 0·5. The œdema rapidly disappeared, the blood pressure fell, and the quantity of urine secreted quickly increased, and within a few days the patient, who was admitted in a pronounced state of toxæmia, was happy and comfortable.

After injection four tablets a day are taken orally *by the patient, but the intravenous* administration should be repeated if the albumin begins to increase in amount and the blood pressure rises. A temporary but pronounced improvement may be expected, but if any anxiety exists labour should be induced, and this can be done with comparative safety as the patient is no longer being overwhelmed by the murky waters of the pre-eclamptic state. If the calcium and alkali treatment were omitted many of these patients would probably develop convulsions during induction of labour.

The public health authorities of Glasgow and the County of Lanark are now using this form of treatment in *all their antenatal centres and* we advise that the administration of these drugs should be started about the fourth month of pregnancy. Not only may toxæmia be thus prevented, but the alkalinity of the urine which is produced may have an inhibitory influence on the activities of the *Bacillus coli communis* and diminish the incidence of pyelitis. Recently it has come to my knowledge that one of my colleagues at the Western Infirmary, Glasgow (Dr. J. A. W. McCluskie), always gives intravenous injection of calcium before using salvarsan in cases of syphilis, for as he finds *it is a reliable* preventive of acute yellow atrophy of the liver—a complication which is liable to arise if salvarsan *alone* be used. This circumstance is additional confirmation of the protective action of calcium in connexion with hepatic metabolism. We have obtained less satisfactory results in the pre-eclamptic state from the intramuscular injection of calcium and consequently we recommend intravenous administration.

SOME POINTS IN THE DIAGNOSIS AND TREATMENT OF THE ACUTE RETROPHARYNGEAL ABSCESS

By N. Asherson, M.B., B.S. Lond., F.R.C.S. Eng.

ASSISTANT SURGEON TO THE CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL; SURGEON FOR DISEASES OF THE EAR NOSE, AND THROAT TO THE QUEEN'S HOSPITAL FOR CHILDREN

An acute retropharyngeal abscess presents behind the posterior pharyngeal wall, medial and posterior to the posterior faucial pillar, in the potential space between the prevertebral fascia and the fascia investing the pharynx. This chink extends laterally behind the carotid sheath and passes under the sternomastoid muscle towards its posterior border. It contains loose tissue which enables the pharyngeal wall to be raised easily and to a great extent away from the posterior vertebral support by any collection of pus.

For examination of the throat the patient faces directly forwards. If the head is deviated to one side, the transverse process of the upper cervical vertebra forms a prominence behind the posterior pillar, and so simulates a retropharyngeal abscess. This prominence may be very striking.

The abscess may thrust forward the posterior pillar and, where the tonsils have been previously removed, this bulge may simulate an inflamed tonsil. As the anterior faucial pillar invariably atrophies after tonsillectomy, the bulge described is, to the non-discriminating observer, behind a pillar (mistaken for the anterior pillar) and the resemblance may be

Case 2.—A female, aged 28, had all her teeth extracted der ether anæsthesia on Feb. 13th, 1932. She became ry ill about March 1st, and on March 14th I was asked to e her by her medical attendant, who wrote: "She is, hink, suffering from acute pulmonary tuberculosis." Her mperature was 103·2°, and her pulse-rate 140 per minute, d an offensive smell was obvious on entering the room. he sputum was brown, blood-stained, and evil-smelling. hysical examination located an extensive lesion in the ght lower lobe, the signs being those of consolidation of ng tissues, with commencing softening. Examination the sputum at the Derby County Laboratory showed reptococci, pneumococci, *Micrococcus catarrhalis*, a large umber of fusiform bacilli and spirochætes, but no tubercle acilli.

The patient was moved to hospital, where the temperature radually fell and the condition improved under general reatment. N.A.B., 0·15 g., was given intravenously on arch 23rd; the patient refused a second injection. By arch 26th the temperature had dropped below 98·4°, and he pulse-rate was under 90 per minute. The sputum isappeared altogether, and none could be procured for a e-examination.

Case 3.—A male, aged 30, a cooper by trade, was referred to me by his panel doctor on March 1st, 1932, as possibly a case of pulmonary tuberculosis. He gave a history of an influenzal attack with bloody foul-smelling expectoration seven weeks previously. Patient stated that he had not been well for years. A sister had died of pulmonary tuberculosis some 12 years before. All the teeth of the upper jaw had been extracted under local anæsthesia three years previously. Pyorrhœa was present in the gums of the lower jaw. The pulse and temperature were normal. Physical examination of the chest suggested generalised pulmonary fibrosis, but the skiagram showed no definite lesions nor any "leafless tree" shadows. Examination of sputum was negative for tubercle bacilli, but showed streptococci pneumococci, Vincent's fusiform bacilli, and spirochætes. The patient continues under treatment.

Case 4.—A male, aged 59, a discharged soldier of the regular army, now a mill labourer, was referred to me on April 27th by his panel doctor as "suspected chronic phthisis." The patient complained of loss of weight, night sweats, and severe cough, without much expectoration. His temperature was 99°, and his pulse-rate 120. Loud rhonchi were present over both sides of chest, with moist râles towards the bases. He had lost many teeth; those that were left were carious, and the incisors were loose and embedded in pyorrhœic sockets. The sputum was negative for tubercle bacilli, but contained streptococci, pneumococci, and fusiform bacilli and spirochætes in large numbers.

A skiagram showed a generally hazy chest. The patient gave a history of gonorrhœa and buboes in India 35 years before, and a Wassermann reaction was positive on May 12th, 1932.

The county pathologist reports: "The spirochætes are indistinguishable from those usually associated with Vincent's angina. *Dark-ground illumination* failed to show any other variety." The patient was referred back to his own doctor for antisyphilitic treatment. He is already back at his work and has gained several pounds in weight.

COMMENT

It is to be noted that three of these four cases were referred to me as suspected pulmonary tuberculosis; one had actually been notified as tuberculous. There is, I fear, little doubt that in the past many so-called "T.B. minus" cases of tuberculosis were pulmonary infections of this type. Looking back over an experience of 14 years as a tuberculosis officer, this type of pulmonary disease now seems to stand out plainly enough to be recognised clinically. Dr. Smith writes: "After proper allowance is made for pleomorphism it is about as easy to pick out a case of this disease in the wards of a hospital as one of tuberculosis." The cavities of carious teeth, pyorrhœic tooth sockets and, according to Dr. Roodhouse Gloyne, the crypts of unhealthy *tonsils* seem to be the natural home of *B. fusiformis* and *Spirochæta vincenti*. The ecology has *not* been fully investigated, but the organisms appear to exist in symbiosis. Tunnicliff and Smith observed, however, that pure cultures of fusiform bacilli can develop into spirilla-like forms.[1]

In three of my cases wholesale removal of teeth had been undertaken for pyorrhœa and caries—in the two acute cases within a fortnight of the onset of the symptoms, in one chronic case three years previously. In the acute cases general ether anæsthesia was employed, and it seems reasonable to conclude that the infective material was aspirated into the bronchi during anæsthesia. The fourth case had a mouthful of septic dental stumps. Smith writes that the spirochætes are absolute anaerobes and disappear very quickly from the sputum when it is exposed to the air; consequently the examination should be made within 30 minutes after the material is expectorated. If, however, the sputum is bloody, the blood protects the spiral organisms, and they may be found even 10 or 12 hours later. In my four cases the sputum was forwarded by post to the Derbyshire county bacteriological laboratory, and a period of 18 to 24 hours elapsed between the expectoration and the examination. The stain used was dilute carbol-fuchsin, without heat. Smith emphasises the *necessity for* washing the sputum before examination, doubtless in order to safeguard against buccal contamination.

TREATMENT

Smith[1] and Scott Pinchin and Morlock[3] recommend treatment by arsenical preparations. In one of the acute cases reported here two intravenous injections of stabilarsan, 0·3 g. and 0·45 g., were given, and this treatment seemed to have had a specific curative effect. The other patient had recovered from the acute stage before an injection of 0·15 g. N.A.B. was given. Where a definite abscess can be localised and drained through the bronchoscope, direct injection of a suitable dose of the drug directly into the abscess cavity has been suggested, care being taken that none of the drug escapes into the trachea or bronchi, as it is intensely irritating. Syphilologists, however, warn us against such a practice, on the grounds that local inflammation and sloughing might occur and that arsenicals produce their action on the spirochæte indirectly, through the medium of a toxalbumin. If untreated, the condition appears to persist as a chronic purulent or bloody bronchitis with offensive expectoration and eventual formation of bronchiectatic cavities.

My thanks are due to the county bacteriologists, Dr. Sheila M. Ross and Mr. C. F. Peckham, for their help and suggestions, and to Drs. Sawdon and Drabble for their notes on the progress of their cases.

A CASE OF CHRONIC TETANY

By Desmond Curran, M.B. Camb., M.R.C.P. Lond., D.P.M.
ASSISTANT MEDICAL OFFICER, THE MAUDSLEY HOSPITAL, LONDON
AND
L. C. Cook, M.R.C.S. Eng., D.P.M.
LIAISON OFFICER, LONDON COUNTY COUNCIL MENTAL HOSPITAL SERVICE

The case here recorded is of interest because the symptoms were such that for several years the diagnosis of a "functional" disorder was maintained.

The patient, a single woman aged 40, was admitted to the Maudsley Hospital from the out-patient retropharyngeal abscess which was visible when the tongue was depressed. The abscess was incised from above as far down as the arytenoids and recovery was rapid.

---

[3] Pinchin, A. J. Scott, and Morlock, H. V.: Proc. Tuberc. Assoc., Tubercle, 1932, xiii., 374; and personal communications.

CASE 4. *Bilateral acute retropharyngeal abscess, simulating Hodgkin's disease.*—A male, aged 28, who had suffered from dysphagia for a few weeks, had a bilateral cervical swelling the size of a golf ball. At the angle of the jaw on each side was an enlarged gland, with one or two smaller satellite glands. The mass was firm, non-fluctuant, and free from tenderness. The posterior wall of the pharynx, medial to the left posterior pillar, was elevated by a globular mass, very hard and painless. The tonsils were small, septic, and embedded. The Wassermann reaction was negative. A record needle attached to a syringe was inserted into the pharyngeal swelling without any anæsthetic, and the aspiration revealed pus. The abscess was drained *via* the pharynx, and the entire cervical mass on that side subsided. A finger inserted through the pharyngeal opening entered the cervical mass. The glands on the other side subsided, but within three weeks another cervical swelling arose on the right side, forming a marked bulge occupying the masto-mandibular recess and reaching down as far as the angle of the jaw, where another discrete gland, the size of a walnut, was present. There was no tenderness and the patient was well. Behind and medial to the posterior pillar of this side was a swelling, free from tenderness, hard and covered by normal mucosa. At the end of a week it was in *statu quo*. In view of the previous abscess, a needle was inserted into the retropharyngeal mass and the patient gagged violently, with the result that the syringe attached to the needle filled with pus immediately, without any manœuvring. The blood count was 58,000 white cells. The abscess was incised via the pharynx.

In this case the diagnosis of suppuration was only possible after using the exploration needle and syringe. Clinically the swelling resembled a lymphadenoma, in view of the multiplicity, size, and physical signs of the glands. A section from the gland removed at the time of drainage eliminated this disease. Within 24 hours the white cell count was down to 12,000. After another cervical abscess, which was incised, convalescence was protracted but normal.

CASE 5. *A posterior "quinsy" simulating a retropharyngeal abscess.*—A female, aged 30, had a sore-throat and dysphagia for a few days, with pyrexia. The right tonsil was pushed forward by an inflammatory mass, apparently behind the posterior pillar. The anterior pillar was normal. A collection of submucous pus was evacuated. This cured the abscess, which was not deep to the fascial pharyngeal investment and therefore must be looked upon as a "posterior quinsy," in view of its proximity to the tonsil capsule and the fact that it was submucous.

The true acute retropharyngeal abscess is well behind the tonsil, and lies behind the posterior pillar, outside the fascial covering of the pharynx. It is not in juxtaposition with the tonsil capsule as is a quinsy.

CASE 6. *Retropharyngeal abscess in an infant simulating laryngeal diphtheria; diagnosis only made by direct laryngoscope.*—An infant was admitted gravely ill from infection, with a history of recent respiratory embarrassment. When she fell asleep the jaw fell back and respiration ceased. Holding the jaw forward
The condition was that observed
when, unless the jaw is held forw
and breathing is impossible. Tl
phenomenon was obscure. Laryngeal diphtheria was assumed and serum administered.

Direct laryngoscopy was made,* the infant being rolled in a blanket and its head drawn over the edge of the bed. A globular centrally situated swelling with its summit opposite the larynx, invisible with the ordinary tongue depressor, was observed. It was a retropharyngeal abscess, and the centrally placed eminence acted as a stopper to the larynx. With the onset of sleep the larynx fell back and was completely occluded by the swelling. The abscess was incised as described above, without an anæsthetic, the head being held by an assistant. The breathing was restored to normal and the child had its first sleep for days. Convalescence was uneventful.

SUMMARY

1. Cases of acute retropharyngeal abscess are recorded, and a distinction is drawn between this condition and a "posterior quinsy."

2. The use of an exploring syringe and the use of the direct laryngoscope as an aid to diagnosis are described.

3. A description is given of a tranquil method f incising and draining the abscess through th pharyngeal wall.

---

* To minimise any chance of the observer having diphtheritic material coughed at him, I use a laryngoscope with a celluloid screen attachment made by the Medical Supply Association.

Clinical and Laboratory Notes

FOUR CASES OF FUSO-SPIROCHÆTAL DISEASE OF THE LUNGS

BY PATRICK HEFFERNAN, M.D. N.U.I.
TUBERCULOSIS OFFICER, DERBYSHIRE COUNTY COUNCIL

THE literature of pulmonary fuso-spirochætal disease—i.e., the infection set up by the symbiotic organisms associated with Vincent's angina—is now very considerable. David T. Smith,[1] who had reported 14 cases in New York, reviewed the whole subject in 1928 and gave no less than 128 references. With the exception, however, of the cases published by Campbell and Dyas [2] in 1917, which appear to have occurred amongst Canadian troops in England, no British cases had been published up to 1928. In my latest copy (old editions accumulate in 30 years' professional life) of "Taylor's Medicine," the thirteenth edition, dated 1925, the condition is not mentioned. Recent work in the London chest hospitals has, however, demonstrated that the condition is a common one. The use of the bronchoscope, in particular, has greatly helped in clarifying our conceptions and in demonstrating the parts played by anaerobic organisms, often acting in symbiosis, in the causation of bronchial and pulmonary disease.

THE CASE RECORDS

The notes of four cases which I have met during the past three months in the north-west of Derbyshire may be of interest, if only in drawing some attention to a common pulmonary condition which is, I believe, frequently mistaken for tuberculosis, and may, for example, sometimes constitute the "infective" element in "infective silicosis":—

CASE 1.—A female, aged 42, had several teeth removed under light ether anæsthesia on Feb. 21st, 1932. On March 1st she called in her medical attendant as she had been feeling ill for two days; her temperature was 100° F., but she had no objective signs. Three days afterwards the temperature was 103·5°. On March 4th an irritating cough came on and the patient complained of an unpleasant taste in the mouth. On March 5th she coughed up a quantity o purulent offensive material. This expectoration becam copious in the following days, and the offensive smell becam obvious on entering the room.

I saw the patient in consultation with her medica attendant on March 9th. Physical examination failed t locate any definite abscess. Examination of the sputum at the Derby County Laboratory showed streptococci pneumococci, *Micrococcus tetragenus*, gram-negative bacilli and Vincent's fusiform bacillus with spirochætes, in larg numbers. I recommended postural drainage, creosot perles by the mouth, and, on the suggestion of Dr. S. M Ross, arsenical preparations intravenously.

Dr. G. Sawdon, the patient's medical attendant, report the subsequent course as follows: "Stabilarsan, 0·3 g. was given intravenously and some improvement wa obtained, but the condition was still maintained, wit paroxysmal attacks of coughing which were very exhausting and subsequent evacuation of foul-smelling pus which wa now dark anchovy coloured. On March 27th a furthe injection of 0·45 g. of stabilarsan was given intravenously By next day the cough and expectoration had ceased an the temperature was normal; the patient then made a uninterrupted recovery." No sputum is now available fo further examination.

REVIEWS AND NOTICES OF BOOKS

n Introduction to Analytical Psychotherapy

By T. A. Ross, M.D., F.R.C.P.E., M.R.C.P., Medical Director of the Cassel Hospital for Functional Nervous Disorders. London: Edward Arnold and Co. 1932. Pp. 203. *10s. 6d.*

In his preface Dr. Ross expresses a fear that the achings of Freud may become lost to our profession, e Freudians having given up the general physician unteachable. Yet he would surely agree that ny modern views about the psychoneuroses inevitably ear the mark of Freud's influence, even if acknowdgment may sometimes be lacking. It is true that sycho-analytical publications are rarely planned or the ordinary medical reader and that he cannot e expected to go to the fountain head and study or himself the development of Freud's work, ascinating as that is. In this book is a rich store of bservations designed both to develop psychonalytical theory—as Dr. Ross is compelled to see t—and to illustrate therapeutic methods. Dr. Ross udges theory in the light of his own experience nd his methods are the application of psychoanalytical knowledge rather than psycho-analysis proper; this attitude is indicated in the title of the book.

A survey of the views of Janet and Morton Prince, with a brief dismissal of Adler's contribution to psychopathology, leads on to a demonstration of the necessity of a theory of the unconscious, which conveniently sums up a mass of observations and has the same validity that is attached to other scientific conceptions. Things happen as if the unconscious exists and, says Dr. Ross, if it helps anyone the proviso "if indeed it exists" may be understood each time the expression is used. Chapters on dreams and sex problems, transference, fixation, and regression combine theory with practice, and a discussion of the dangers of analytic investigation puts them into their proper relation with the dangers attached to any other active medical or surgical procedure. The chapter on technique provides no cut-and-dried rules but a description of difficulties and pitfalls and the way to avoid them; it is useful not only to the would-be psychotherapist but to the physician whose aim is to obtain a true picture of the patient's troubles. The orthodox psycho-analyst will, perhaps, find in the brevity of the description of free association an explanation of Dr. Ross's failure to satisfy himself of the universality of certain contents of the unconscious, for their discovery is claimed to depend upon a painstaking use of this method. Opportunity for such criticism is bound to arise when a worker on this big subject only accepts what he himself finds; it does not lessen the value of the book which, with no glossing over of difficulties, fulfils in simple and straightforward fashion the promise of its title.

An Outline for Boys and Girls and their Parents

Edited by Naomi Mitchison. London: Victor Gollancz. 1932. Pp. 928. With 166 illustrations. 8s. 6d.

This is an attempt to set out the foundations of knowledge for the benefit primarily of children, but the writers have had their eyes also upon parents to whom resort for explanations or supplementary information may be had. The plan of the book is ingenious. In the first place the appeal is to the individual reader, and to him it is explained what he is in the chapters on physiology, biology, and chemistry. His place in the general scheme of things is then made clear by the chapters on chemistry again, on physics and on applied biology; and now, knowing his place on earth, he is invited to consider that earth as it was and is, and its position in cosmogony. Brief principles of astronomy follow. After the scientific section, which occupies the first third of the compendium, a group of writers attack the huge task of telling the story of civilisation from the primal great discoveries of mankind down to the present day, with considerations of future problems based upon ancient experience and its progressive developments. A series of chapters deal with the physical and social story, with the arrival of the family unit and its inclusion in larger groups, and with the rise of the national idea. Mesopotamia, Greece, Egypt, and Rome are shown to have played their assorted parts in the evolution of the world as we now know it, being influenced by various aspirations for good and ill, and the tenets of different religions. A chapter is devoted to the occurrences of the last 30 years, in which the Great War is discussed as a sequel to the national strifes engendered by material rivalries, when the plea for international activities, conducted upon settled plans, is advanced forcibly. This section closes with chapters on the machinery of society as exemplified by the practices of law and its relation to government, and by the power of money with its economic implications. A third section, the shortest, deals with the arts, and is designed to inculcate in the mind of the young reader their value in making life so much more worth living.

The scientific section is thoroughly well done. Within the limits of space prescribed, the knowledge of to-day is outlined accurately, what matters much being drawn with a firm hand, details irrelevant to an outline being duly omitted. The manner in which the difficult subject of physiology is dealt with by Prof. Winifred Cullis, in collaboration with Miss Evelyn Hewer, D.Sc., forms a sound example of the right way to introduce new lessons to young minds, and the same congratulations can be extended to Mr. John Pilley, D.Sc., who, however, expounds chemistry in a different manner. He draws no outline of the whole subject, but explains with great skill the fundamental structure upon which modern chemistry rests, giving the best brief account we remember to have read of the properties of matter, and of the researches which have led up to their discovery.

The value of the social section of the book is more open to debate, as the lessons which are inculcated here are dependent frequently upon opinions and not upon scientific results. The opinions, even when widely diverse fields of social evolution and organisation are under discussion, display great unity, and the treatment recommended for the ills under which society suffers is usually drastic, perhaps too drastic. The medical mind must hold that meddlesome medicine may prolong disease, and that remedies that would be of value in a later stage may be less than useless when applied prematurely. A passionate desire to do the best by the patient is not accepted scientifically as an apology for malpraxis. Two essays in this section stand out for their practical worth, that on law and government by Mr. G. R. Mitchison, and that on economics by Mr. Hugh Gaitskell. Mr.

department on Sept. 8th, 1931. She had come up that afternoon complaining of pains in her stomach and "drawing" of her arms and fingers, with consequent depression.

The family history was negative.

Past history.—She was the fifth of eight surviving children of a family in poor circumstances, but she never experienced actual want. Her early development was normal, but she became "weak in the legs" at the age of 4 and was considered delicate as a child. Nevertheless she was able to attend school regularly, though she only reached standard IV. She entered domestic service at the age of 15, and was a regular and steady worker until she gave up her last position shortly before the onset of the present illness. She was of a quiet, sensitive, and retiring disposition, with few interests, yet contented with her lot. She always tired easily, but her physical health was good and she was never in hospital. Her periods did not start until the age of 19. They were quite regular. She had some dysmenorrhœa when young. Her sexual life seemed devoid of interest or episode.

History of present illness.—She gave up work some five years before admission to look after her mother and sister who were ill. This preyed on her mind and at about the same time the symptoms developed. There was considerable variation in their severity, and she spent months at a time free from cramps or pain, but never felt fit enough to start work again.

The attacks from which she suffered had in general the following characteristics :—

About once a month, usually just before her periods, though occasionally in between them, she would suffer from a "squeezing" pain in the stomach to be followed by shivering and diarrhœa. This would last for several days and be a sign to all that an attack was due. Her fingers would then go "cold and black and start doubling up." These painful cramps would last two or three days and sometimes be accompanied by twitching of the face and in the region of the elbows. Sleep became difficult, and she would cry with pain. The cramps would then pass off rather suddenly leaving an ache.

She became run down, lacking in interest, low-spirited, and prone to weep easily. She also became very thin. Her condition was attributed both by herself and by her medical attendants to "nerves." The attack which brought her up to hospital was the worst she had experienced, and had started four or five days before admission. Her period was about due.

Condition on admission.—She was a pale, wan, thin, puny woman, looking older than her age. Her manner was quiet, resigned, and pleasant. She was a good witness, if allowance be made for her rather low intelligence and limited vocabulary. Her general physical condition was poor. Height 4 ft. 8 in., weight 6 st. 4 lb. Her hair was rather sparse and turning grey, her jaws edentulous. Her lungs, heart, and abdomen showed no abnormalities. Her arteries were not thickened. Blood pressure 110/75. She was very knock-kneed and showed well-marked bowing of the right tibia, such as results from rickets when a child.

Tetanic spasms.—She showed clearly the classical features of tetany. Her upper extremities were flexed at the elbows, wrists, and fingers, the tendon of palmaris longus standing out prominently. She was unable to extend the wrists or fingers and showed flexor jerkings, together with much pain and discomfort, when her blood pressure was taken. Chvostek's sign was present. There were no signs of affection of her lower extremities, except for some slight increase of the tendon reflexes. Spasms, when not actually present, could easily be produced by a few minutes over-breathing.

Special tests.—Urine normal. Blood count: very slight anæmia (circa 4,250,000 red cells per c.mm.). Wassermann reaction negative. Serum calcium 6·5 mg. per 100 c.cm. Plasma inorganic phosphorous 3·1 mg. per 100 c.cm. Fæces normal. X rays: evidence old rickets, especially right *tibia*, ? some rarefaction. Eyes (Mr. R. Foster Moore) fundi normal. Lenticular opacities present.

Progress.—Definite carpopedal spasms developed, and continued fairly frequently for ten days after admission. In the intervals they could easily be elicited by over-breathing, and Trousseau's and Chvostek's signs continued to be present. The serum calcium remained between 6·5 and 6·7 mg. per 100 c.cm. and inorganic phosphorus between 3·1 and 3·4 mg. Intravenous calcium chloride gave temporary relief. She was given lactate grs. 10 t.d.s. and lactose grs. 30 daily in milk on Sept. 25th. The spasms began to diminish rapidly in frequency and severity, and were absent after Sept. 29th. On that date the serum calcium was 8·8 mg. and the plasma phosphorus 3·4 mg. Phosphatase (Kay) 0·25. Good progress continued and on Oct. 5th, when her calcium was 8·6 and her phosphorus 3·7 mg., Trousseau's and Chvostek's signs were negative, and carpopedal spasms could no longer be produced by over-breathing. Despite the return of menstruation on Nov. 2nd, her calcium and phosphorus were respectively 10·5 and 3·25 mg. She was discharged on Nov. 5th, having gained a stone in weight and vastly improved in health and spirits.

After her discharge she attended the out-patient department periodically until about two months ago and has been keeping well. Her periods have been regular and unaccompanied by tetanic symptoms. She has had occasional slight aching of the hands and feelings of languor, not particularly associated with menstruation. She has continued with calcium lactate and lactose.

COMMENT

As psychiatrists, we feel some diffidence in reporting yet another case in which a definite physical disease had been overlooked and the erroneous diagnosis of a purely "functional" disorder maintained. The mistake is too commonly the other way round. It was comparatively easy to make the correct deductions when the patient was seen in actual tetanic spasm, but it appears that no physician had had this opportunity before. Yet it is possible that a little more psychiatric interest, the taking of a more detailed history and a more exact searching inquiry into all circumstances of the attacks, would have roused doubts, and led to the correct diagnosis at an earlier date. The readiness of the patient to accept a "nervous" origin for the complaint might in itself have afforded grounds for suspicion. As it was, the history of domestic worries coinciding with the onset appears to have been accepted too readily as supplying a satisfactory psychogenesis, so that further interest lapsed, though at one period the change in colour and local discomfort in her hands suggested the diagnosis of some vasomotor disorder allied to Raynaud's disease. Her complaint was certainly suggestive of such a condition.

Donald Hunter,[1] in his Goulstonian lectures for 1930, has reviewed the literature and summarised the knowledge at present available of disorders in calcium and phosphorus metabolism. Our case seems most closely allied to the so-called idiopathic steatorrhœas of adults, which is supposed to arise from a defect in the absorption in vitamin D. It has many features in common with one of the cases which he describes under this heading. Both had a small structure and poor physique, evidence of past rickets, loss of weight, bony rarefaction, lens opacities and low serum calcium, together with attacks of tetany. It is true that our case had no diarrhœa whilst in hospital, and the fæces were not abnormal. There was, however, a definite history of such symptoms. With such a history the diagnosis of steatorrhœa is the most probable, though a somewhat lower figure for inorganic phosphorus might have been expected.

As regards treatment, irradiated ergosterol and fat restriction were not tried, as the case did well on calcium lactate and lactose.

Our thanks are due to Dr. Edward Mapother, medical superintendent of the Maudsley Hospital, for permission to publish this case.

When the ng begins to break up, asbestosis bodies are found the sputum in clumps which represent alveoli.—he Pathological Changes Produced in the Tissues by orrosive Sublimate, with Special Reference to the arly Phases of Cell Degeneration and to Changes in he Blood Fat, by R. F. Ogilvie (Edinburgh). In the iver, kidney, and heart muscle the mitochondria reak up into granules which diffuse throughout the ytoplasm and form the granules characteristic f cloudy swelling. There is an immediate and nexplained rise in the blood fat, followed by a fall nd a second rise.—The Red Cells in Microcytic Anæmia (Witts), by C. Price-Jones (London). The condition of the red cells before, during, and after cure by iron salts is described by the author's well-known methods. The differentiation of anæmic from orthochromic cells is particularly interesting, and the proportions of the two kinds are a good index of the state of the patient.—Ligation of the Common Bile-duct, by G. R. Cameron and C. L. Oakley (London). Early focal necroses are healed. There is a great proliferation of bile-ducts which surround, invade, and disorganise the lobules. A divided bile-duct may reunite. Full historical account and literature.—Some Observations on the Eosinophil Cell, by J. H. Biggart (Belfast). Tissue eosinophils are emigrated blood leucocytes which are, in adult life, found only in the bone-marrow. Local eosinophilia can be produced in guinea-pigs by the injection of proteins or peptones, but not by amino-acids.

ERRATUM.—The price of the book by Mr. Arthur G. Wells, entitled "The Discharging Ear," which was reviewed in THE LANCET last week, is 2s. 6d., and not as stated.

BRITISH MEDICAL ASSOCIATION

CENTENARY MEETING IN LONDON

(Concluded from p. 684)

SECTION OF DISEASES OF CHILDREN

Bronchiectasis

Prof. CHARLES MCNEIL (Edinburgh) said that with the introduction of intratracheal injections of lipiodol in 1922 a precise study of the morbid anatomy of bronchiectasis in the living subject became possible, and Findlay and Graham in Glasgow in 1927 showed radiographically different degrees and types of dilatation in children. Recently new methods of treatment by surgical procedure and bronchoscopic lavage had been attempted. The condition usually dated from an acute respiratory illness (often measles or whooping-cough) in early childhood. The cough persisted after the illness, and later became paroxysmal; bouts occurred especially on waking, and often ended in vomiting. Sputum might be copious or scanty; and in children was generally not fetid. Free hæmoptysis was uncommon in childhood, though recurrent hæmoptysis might occur in older patients. At times the cough might disappear entirely, but the child was subject to exacerbations of cough with pyrexia. The general health was surprisingly good. Physical signs were often less reliable than symptoms in diagnosis, but variability in the auscultation signs was significant. Prof. McNeil described and illustrated two types of bronchiectasis: unilateral bronchiectasis with massive fibrosis, the more benign type, and the commoner bilateral type. The milder cases of the bilateral type shaded off into chronic bronchitis with fibrous changes in the bronchial wall. His experience suggested that if children survived the first year or two after the condition developed the chance of survival through the rest of childhood was good, and an active working life was often possible. The condition might remain stationary over a number of years. Post-mortem room observations led Prof. McNeil to believe that the primary change in early bronchiectasis was an intense inflammation of the bronchi which destroyed their walls, rather than fibroid changes in the lung substance.

Medical treatment was only palliative, but the most effectual was daily postural drainage, the child lying prone for at least half an hour on a steep inclined plane. Possibly with improved technique for bronchoscopic lavage a real advance in treatment might be achieved. The same applied to radical surgical treatment, the results of which hitherto had not been encouraging.

Dr. J. H. THURSFIELD (London) held that bronchiectasis, as described by Laennec and as demonstrated by lipiodol, was an advanced stage of a common condition—namely, fibrosis of the lung—and he suggested that the term bronchiectasis should be dropped. In most cases in which fibrosis had occurred in the lung there was some dilatation of bronchioles, and where this was only slight and not demonstrable in radiograms recovery often occurred.

Dr. STANLEY GRAHAM (Glasgow) said that any explanation of the ætiological mechanism must take into account the shrinking of the affected side due to fibrosis which almost invariably occurred. He believed, like Dr. Thursfield, that bronchiectatic dilatation was the direct result of pulmonary fibrosis. Nearly all children with bronchiectasis were markedly under normal height, and their slow growth probably in part explained their fairly good nutrition. He agreed that postural drainage was in most cases the best available method of treatment.

He had had the opportunity of re-examining with lipiodol and X rays 14 children (out of his series of 23) after an interval of three to six years, and six were apparently either stationary or improved. Six others of the series had died.

Mr. J. E. H. ROBERTS (London) gave an account of bronchiectasis from the surgical aspect. The term was used to cover very different clinical entities, including a condition which was congenital in origin. Whether or not radical surgical treatment was eventually attempted, palliative measures must first be adopted to get the bronchial tree as dry as possible. Bronchoscopy might be helpful, since a stricture favouring stagnation of discharge might be removable and aspiration might produce more healthy bronchioles. Radical treatment involved either collapse of a lung and of its dilated bronchioles, or lobectomy. The disease must be unilateral for collapse to be employed. He had found it impossible to predict from clinical or radiographical examinations whether or not in an individual case a lung could be collapsed. He showed remarkably good results in certain cases following collapse of lung by artificial pneumothorax, phrenic avulsion, or by thoracoplasty. Lobectomy was a possible method of treatment when the condition affected only one lobe, but had had a mortality of about 50 per cent. Recently a new technique had been employed in Toronto, and 14 successful cases were reported. Mr. Roberts and his colleague Mr. Nelson had operated on two cases by the new method, and he felt that if the method fulfilled its promise lobectomy would be the operation of choice for this group of cases.

Dr. H. TUKE ASHBY (Manchester) agreed that

Mitchison's summary of our legal machinery and analysis of our pattern of government are made beautifully clear by application to a breach of the law that might be committed by anyone—say by any parent for whom the book is written. Mr. Gaitskell explains the controlling power and international flow of money, so that, for example, the meaning of the gold standard and the bank-rate, and the arguments for and against protection become comprehensible. Both the lawyer and the economist are dealing with facts, and by confining themselves to facts may disappoint the "forward-thinking parents and teachers" who, says a strident wrapper, want the book; ordinary parents and teachers will welcome the direct guidance given in difficult places, and may not regret the absence of vague directions to Utopia.

The book is well got up, modestly priced, and profusely illustrated. The labour expended by all concerned in its production should earn substantial reward.

L'occlusion intestinale

By PIERRE MOIROUD, Chirurgien des Hôpitaux de Marseille. Paris: Masson et Cie. Pp. 120. Fr.18.

THIS is an excellent little monograph, written with Gallic clarity and decision. Although the diagnosis of obstruction is well described, the chief object of the book is to give an account of and to evaluate the different methods of treatment; above all to emphasise the modern views which have led to chloride therapy. It can be warmly recommended.

Recent Work on Ptosis

(*Prolapse*) *of the Female Pelvic Viscera*. By E. HESKETH ROBERTS, F.R.C.S. Edin., Gynæcological Surgeon, St. John's Hospital, Lewisham. London: Dickson and Scudamore. Pp. 110. 9*s.* 6*d.*

THE ætiology of prolapse is a subject which periodically gives rise to warm discussion. The anatomy of the pelvic fascia and pelvic cellular tissue is difficult to understand and there is much dispute as to which structures are important in supporting the pelvic organs. Careful descriptions of original anatomical research are few, but recently Amreich has made a magnificent contribution in the new Peham-Amreich "Gynäkologische Operationslehre." Mr. Hesketh Roberts makes no reference to this work although it has attracted great attention. His small book hardly displays the critical estimate of scientific evidence which is to be expected in a modern work, though he has read widely and reviews usefully a great deal of the literature.

Traité de physiologie normale et pathologique

By Prof. G. H. ROGER and Prof. LEON BINET, in the Faculty of Medicine, Paris. Vol. VI. *Circulation.* By Six Collaborators. Paris: Masson et Cie. 1932. Pp. 589. Fr.90.

IN this part of Roger and Binet's treatise on physiology the embryology and anatomy of the heart are briefly described, and the hæmodynamics of the heart-chambers and the mechanism of production of the heart sounds are discussed. A fair account of our knowledge of the circulation through the coronary arteries is given, including a discussion of their innervation. Cardiac automatism and innervation are treated at length, the physiopathology of the heart rhythm is described, and a short section on the electrocardiogram is included. The arterial, venous, and capillary circulations are well set out, and recent work on their nervous and hormonal control is noted. The book is primarily written for physiologists, but the clinician will find it interesting and readable. The style is elegant, but the illustrations and general production do not reach a very high standard.

United States Army X Ray Manual

Authorised by the Surgeon-General of the Army. Second edition. Rewritten and edited by Lieut.-Colonel H. C. PILLSBURY, M.D. U.S.A. London: H. K. Lewis and Co., Ltd. 1932. Pp. 482. 25*s.*

THE first edition of this standard manual was published in 1920 and was the work of a number of collaborators who had gained experience of the needs of radiologists in the war. The result as an elementary treatise was entirely satisfactory. The second edition has been revised and rewritten by Lieut.-Colonel H. C. Pillsbury by direction of the Surgeon-General. It is clear that instructions have been given to restrict the size of the book so that it should be no larger than its predecessor. In this task the author has succeeded, but at a heavy cost, for the scope of radiology has expanded rapidly in the last 12 years. In spite of the omission of sections that were devoted to various obsolete methods of localisation and to X ray therapy, there is so much new material to be included that the author has been placed at a serious disadvantage in his attempt to cover the whole field of radio-diagnosis. Half the book is devoted to X ray physics, technique, and localisation, which leaves inadequate space for a summary of the vast subject. Colonel Pillsbury has followed standard lines and the limited space available has precluded discussion. He has, however, succeeded in including a considerable amount of reliable information and the book gives a useful outline on which to build up a sound general knowledge of radiology.

Journal of Pathology and Bacteriology

THE September number (Vol. XXXV., No. 5) contains the following papers: The Antigenic Properties of Different Fractions of Staphylococcus, by K. W. Goadby (London). The capacity to produce an antibody response gra[illegible] as the organisms are chemically [illegible] Precipitation of Diphtheria Toxoid by Metallic Salts and the Antigenic Value of the Precipitates so Formed, by Margaret Llewellyn Smith (London). Alum compounds of toxin or toxoid are known to be exceptionally good antigens. Other procedures are here tested and goods results were obtained with colloidal aluminium hydroxide, zirconyl chloride, and calcium phosphate.—The Rabbit as a Means of Distinguishing the Human from the Bovine Type of Tubercle Bacillus: the Lesions Caused in the Rabbit by Tubercle Bacilli of the Human Type, by L. Cobbett (Cambridge). Human tubercle bacilli injected into rabbits exceptionally cause either a transient generalised infection or severe progressive lesions.—The Production of Bacteriotropins for Hæmolytic Streptococci by Patients Infected with that Organism, by R. Hare (London). Opsonins for the homologous organisms develop during puerperal infections except in rapidly fatal cases.—The Post-embryonic Development of the Erythrocytes of the Albino Rat, by Christianna Smith (London). A precise quantitative study of the changes in the red cells in infancy. About the time of birth there is a considerable decrease in size and variability and the population of red cells is almost completely changed in the course of a few days.—Primary Round-celled Sarcoma of the Peritoneum, by T. F. Hewer (Khartoum). In a Sudanese of 40.—Tuberculosis of Systemic Arteries with Fatal Rupture: a Report of Two Cases, by H. L. Sheehan and R. Whitehead (Manchester). Of the subclavian and splenic arteries.

emotherapeutic research it was also necessary to ve a potential or reputed remedy, and it was tural that the work should at first have concerned self with substances which were already known to ert physiological or therapeutic action—i.e., with tural alkaloids or their derivatives. This country as doing little chemotherapeutic research considering ie importance of the subject.

The final and crucial test of a drug was its ffect on disease in man, and human experiental therapeutics would require the same rethought, skill, and coöperation as did experients undertaken in pursuit of other sciences. edical students ought to be taught therapeutics, ncluding practical therepeutic investigation, as horoughly as they were taught diagnosis or pathoogy. The experiences of the general practitioner, aken in the aggregate, would greatly assist the dvance of practical therapeutics. Teaching implied eachers; yet the University of Edinburgh was the nly teaching medical school in this country which had a whole-time chair of therapeutics. The problem of discarding useless remedies would remain as long as new remedies were thrust on the market by drug manufacturers who spent money on investigating new compounds, and had to recoup themselves by the profits on a new drug. A manufacturer could now submit a new drug for the consideration of the Therapeutic Trials Committee of the Medical Research Council, which committee was in a position to arrange for a thorough investigation of the therapeutic merits of the drug. If, as a result, drugs were not in future put on the market without reasonable evidence of their worth, the gain would be great. It would be an advantage to have one large hospital concentrating its main energies on therapeutic research and post-graduate instruction. Some organisation was wanted for sifting and promulgating the knowledge of therapeutics. Medical research was increasing, and new journals continued to appear. A man might spend a good part of a lifetime in reading the literature on quinine alone, and the difficulty of coping even with abstracted literature was becoming increasingly great. Prof. Gunn wondered whether it might not be feasible to establish in every country a bureau of pharmacology and therapeutics which would receive direct from publishers a copy of every paper and book dealing with these subjects. Perhaps it might be combined with laboratories for pharmacology and chemotherapy, a hospital for therapeutic research, and a bureau for sifting and promulgating advances in knowledge. There was an elaborate organisation, with a ministry, for the prevention of disease, but as yet no such organisation for its treatment.

Prof. V. E. HENDERSON agreed on the necessity for academic encouragement, but held that the difficulty was to find a pharmacologist able to teach therapeutics. The effects produced by drugs on experimental animals were often very different from the effects of therapeutic doses in man. Eighty per cent. of the diseases the ordinary practitioner saw were "minor complaints," and yet hardly any extensive investigations were being carried out on them. A physician had recently published a paper identifying 27 different varieties of dyspepsia, but when it came to treatment the differentiation made no difference. Team-work was very necessary in pharmacology. There was always difficulty in keeping patients in hospital long enough for extensive pharmacological experiments with adequate control periods. Inmates of asylums and gaols would be useful material when they suffered from diseases. No new remedy should be sold until it had been adequately tested out in a large institution.

THE SUGGESTION VALUE OF DRUGS

Dr. ROBERT HUTCHISON pointed out that therapeutics was not and perhaps never would be an exact science, nor were drugs the only therapeutic agent. Research in physics, chemistry, and biology, not directed to any therapeutic end, might yield results useful to medicine. One of the greatest necessities was a closer alliance between medicine and other branches of science; unfortunately the whole trend to-day was towards splitting-up and isolation. Intensive ad hoc investigation was not, he suggested, a very fruitful way of advancing therapeutics. He asked whether a drug was necessarily useless because it was inert in a normal animal under experimental conditions. A large part of the use of any drug was due to suggestion. Practising physicians most of the time were not dealing with organic disease. It was just as important to deal with the trivial things, largely of psychological origin, in which anything did good if the patient believed in it. It was not the action of sarsaparilla on the body that mattered, but its action on the mind as a vehicle of auto-suggestion. The only final test of a drug was its effect on patients, and there was room for much more investigation in this respect. The ordinary physician was not such a doddering dement as pharmacologists supposed; but he did find it difficult to regard his patient as the pharmacologist regarded his rat, and to make proper control "experiments." No hospital specially limited to therapeutics would overcome this difficulty, or that due to constitutional variations in patients and in epidemics. Therapeutics ought to be better taught—so ought all subjects in the curriculum—but the only way to effect this was to make it a subject in the final examination. The accumulation of knowledge was a subject urgently needing research; science was being drowned in its own excreta. The multiplication of laboratories and whole-time research workers was not desirable. It did not matter whether a drug was discovered in Germany, the Argentine, or Timbuctoo, so long as it was not kept secret.

Prof. E. MELLANBY protested at the suggestion that therapeutics was being drowned in its own excreta. The subject had made great advances; to cure a disease by a drug was as valuable as to cure it by suggestion. The present stage of medical advance was largely due to therapeutics—to the direct attack on disease. Successful treatment had often elucidated ætiology. In fact, therapeutics was so successful that it was tending to leave physiology behind. Clinical observations which did not lend themselves to experimental inquiry did not, however, advance. Pharmacology gave medicine an unprecedented control over disease and had broken down the absurd barriers between biology, physiology, physics, biochemistry, pathology, and medicine. Neither the physiologist nor the pathologist realised that therapeutics was revolutionising physiology and pathology. Either the pharmacologist must extend his province to include the science of the treatment of disease, becoming the liaison officer between the laboratory and the ward, or he must remain the handmaid of physiology. There must be some better communication between the laboratory and the hospital; not all doctors regarded the laboratory worker with suspicion. The pharmacologist should be in charge of beds. He could greatly reduce the drug bill. He used fewer and cheaper drugs than the practising clinician. He since bronchiectasis was rare in adult life children with this condition must either die early or make fair recoveries. He had followed up 27 cases: of 11 cases of the unilateral type only 4 were living, whereas of 16 of the bilateral type 11 were living and doing moderately well. Hence his figures suggested that the bilateral was the more benign type.

Dr. N. B. CAPON (Liverpool) was struck by two facts: (*a*) that the text-book description of bronchiectasis was the description of a terminal condition; (*b*) that this condition was found in hospital rather than in private practice. This suggested that the condition was often preventable. If cough, with or without chronic bronchitis, persisted after whooping-cough, measles, influenza, or pneumonia, or if there were fairly constant crepitations to be heard over one area of lung, great efforts should be made to provide for the child in poor circumstances the dietetic treatment and perhaps climatic change available for the child in better circumstances. He regarded as important measures designed to get good lung expansion after pneumonia or atelectasis. After pneumonia the sound lung should be partially immobilised and the child encouraged to take deep breaths several times daily. If the apparatus were available carbon dioxide inhalation could be employed.

Prof. ARMAND-DELILLE (Paris) described with lantern slides dilatation of the bronchioles occurring in cases of tuberculosis.

Dr. C. P. LAPAGE (Manchester) had analysed 40 cases. Most of these had begun at an early age—some under 4 months—and followed broncho-pneumonia; not many followed measles or whooping-cough. He pointed out the need of dealing with any infection of the upper air passages, whether in the tonsils or adenoids or the nasal sinuses.

Dr. E. FLETCHER (London) drew attention to the association between atelectasis or congenital malformation and the development of bronchiectasis.

Vitamins and Minerals in Diet

Dr. ALAN BROWN (Toronto) described work undertaken by himself and his colleagues at the Hospital for Sick Children, Toronto, on the rôle of vitamins and minerals in growth and resistance to disease. Most ordinary mixed diets, he said, would supply the minerals required by the human body, but the supply in the diet of calcium, iron, and iodine should not be left to chance. To provide a growing child with sufficient calcium (a 10-year-old child required about 1 g. daily) milk must be included in his diet, though leafy vegetables would supply part of the calcium requirement. On the other hand, both milk and cereal were deficient in iron, and this could be supplied in egg yolk, liver, spinach. Iodine deficiency was not a pressing problem in the British Isles. He showed the influence of mineral deficiency and of vitamin deficiency in retarding the growth and lowering the resistance of rats; a deficiency of any of the known vitamins excepting E resulted in loss of weight. For an adequate supply of vitamin D children were ordinarily dependent on the action of sunlight on the skin; but it must be remembered that for as much as five to six months in the year sunlight in this country probably had a low anti-rachitic potency. In an ordinary diet 30 to 60 per cent. consisted of cereals containing little vitamin, calcium, or iron. For this reason a specially prepared cereal mixture with additions—including a sufficiency of calcium, iron, vitamin A, B_1 and B_2, and D—had been used in his hospital for the last two years. A group of children receiving 2 oz. daily of this special mixture grew much more rapidly than did the contr group.

Dr. HELEN MACKAY (London) believed that improving the diet of children offered better prospects of increased health in childhood than almost any other line of approach open to the medical profession. By remedying known dietetic deficiencies resistance to disease could be greatly increased. From observations on infants and young children it was apparent that iron deficiency was very widespread; supply of extra iron to artificially fed babies greatly reduced the incidence of respiratory, gastro-intestinal, and other diseases due to micro-organisms. On the other hand, in a group of infants known to be suffering from vitamin-D deficiency there was increased susceptibility to respiratory infection, but not apparently to gastro-intestinal infections; this diminished resistance could not, however, with certainty be attributed to D deficiency alone, as the diets were not in other respects identical.

Osteomyelitis

A paper on the subject read by Mr. C. P. G. WAKELEY (London) showed the diminished incidence of osteomyelitis during recent years as a result, he believed, of the improved standard of living. He considered that trauma played no important part in its ætiology. Early drainage was essential in treatment. He discussed the surgical treatment of the condition, showing that if a case came to operation early enough the medullary cavity need not be opened. He showed radiographically the excellent result obtained in a case of advanced disease in which diaphysectomy of the tibia followed later by bone grafting had been carried out. His rule was to operate as early as possible on osteomyelitis of bones near the surface, whereas when dealing with early osteomyelitis of the femur he preferred to wait.

SECTION OF PHARMACOLOGY AND THERAPEUTICS

AT a meeting of this section the chair was taken in turn by Prof. R. STOCKMAN, Prof. A. J. CLARK, Prof. V. E. HENDERSON, Vice-Presidents, and Prof. J. A. GUNN, President. Prof. GUNN read a paper on the

Outlook of Research in Therapeutics

For convenience, he said, he would consider research in therapeutics from the three angles of experimental pharmacology, chemotherapy, and experimental therapeutics. Modern medicine had acquired an unwieldy heritage of drugs which had been first tested by direct observation of their effects on disease in man, and there had never yet been any deliberate and concerted plan to rid medicine of the incubus of spurious remedies. Pharmacological research was in many ways inseparable from physiology, but it could not be adequately treated as a mere apanage of physiology. The bulk of pharmacological research could never become specialised, and the pharmacologist must have a wide training in physiological technique, and must at the same time maintain a knowledge of the diseases in which his drugs were used. It would become less and less possible for a man to be both a physiologist and a pharmacologist.

The only possible way of determining the curative value of a drug was to determine its action on the complex of host plus parasite. The reason why the advance in the treatment of trypanosome infections had been so rapid was that they could readily be produced in small laboratory mammals, and their parasites were easily recognised in the blood, so that the course of the infection could be followed. For

VITAMIN D IN THERAPEUTIC MIXTURES

A tasteless, inodorous suspension of vitamin D (Calciferol G L.) equivalent to 50 times its own volume of high-grade cod-liver oil Being miscible with water and having no incompatibilities, Ostelin Liquid can be prescribed in medicinal mixtures No other vitamin D preparation has this outstanding advantage.

might not be a great clinician; he must take help from and give it to his colleagues. He should not take fees, his object being solely to discover and investigate. Nor should he devote time to teaching; the work of investigation was very difficult, while teaching was easy, and thus a temptation to the tired worker. The laboratory must come first; ideas from animal experiments could be tested on patients, but fundamental research could not be initiated on them.

Dr. J. H. BURN thought it was quite time that a physician emphasised the psychological importance of drugs, and suggested that a class of "psychological" drugs should be frankly recognised. It might be argued that the doctor must continue to believe in them, but at any rate the very expensive ones might be cut out. He agreed that therapeutics might replace pharmacology in the examination list; much of the present pharmacological teaching was useless. Many things in therapeutics could only be appreciated at the end of the course. A long training was needed before a man could tackle a research job properly, and this training could only be obtained by six or seven years in a laboratory. The progress of the last 25 years was astonishing, and much of it had come from clinical observation. Contact with patients suggested all sorts of things that never occurred to the laboratory worker.

Prof. F. L. PYMAN pleaded for more research in pharmacology, and for close coöperation between the research chemist and the pharmacologist; any promising chemical compound ought to be examined in the pharmacological laboratory from many points of view. A body similar to the Council of Pharmacy and Chemistry of the American Medical Association might be useful here; this body approved a drug before it could be advertised in the journal of the association.

Prof. A. J. CLARK said that he advised his students not to emphasise too much the element of suggestion, as the lusty chiropractor was often more successful than the qualified practitioner in this direction. Great as had been the advances, he wondered if they ought not to have been greater, comparing them, for instance, with the development of wireless, or even of antimalarial therapy in the last three years. Organised team-work on a large scale might detect fine differences between drugs and work up the efficiency of the drugs at our disposal.

Prof. F. R. FRASER defended the practice of requiring research professors to teach and sit on committees; this work widened their views. Help in interfering with disease came from all quarters, but in only a few diseases could real interference be effected as yet, and the pharmacologist could only help the patient to break the process himself. He gave some account of the work of the Therapeutic Trials Committee.

Prof. W. J. DILLING thought that no defence of the experimental method was necessary, and urged the section not to overlook the wealth of research material in municipal hospitals.

Prof. D. CAMPBELL said that researchers were born, not made, yet much could be done to improve them. They should have a sound training in physiological methods, and particularly on the way in which physiological and pathological processes could be modified by physical and chemical means. For this, laboratory training was not sufficient. There was at present very little opportunity for pharmacologists to do therapeutic research; perhaps because authorities did not care to entrust wards to men with no clinical training.

Prof. R. STOCKMAN thought that the general practitioner had brought the treatment of minor ailments almost to perfection and needed very few drugs. Prof. Stockman's attitude to drugs was that of Polonius: "Those friends thou hast, and their adoption tried, grapple them to thy soul with hoops of steel; but do not dull thy soul with entertainment of each new-hatch'd, unfledged comrade." Better training must begin with the student. Most, if not all, of his present text-books could advantageously be discarded; they gave very little real help in therapeutics. It would be good for the pharmacologist to be faced by the hard facts of disease. He must, however, be a man trained in chemistry; doctors, as a whole, were badly trained in the exact sciences.

Prof. GUNN briefly replied, defending the ad hoc experiment.

Dr. J. H. SHELDON read a paper on the

Effect of Copper and Manganese on the Therapeutic Action of Iron

He said that recent work had shown that various metals were widely distributed in human protoplasm. Copper was a universal and essential constituent. Without copper the body was unable to use iron, and manganese was necessary for reproduction. Pure iron could not cure iron-deficiency in rats, but when a little copper was added the anæmia was cured; nothing else would do instead. An obvious application lay in the nutritional anæmia of infants. The human baby seemed to need about 0·5 mg. of copper daily. Young tissues seemed to contain more copper than adult tissues. Copper probably played an important part in growth, and increased the demand for iron. It was therefore desirable to give larger doses of iron with copper. At birth there was a large reserve of copper in the liver; copper and iron were the only metals stored in the liver during fœtal life. The infant depended on this store to prevent nutritional anæmia during its milk-diet period; therefore the mother should be supplied with these metals during pregnancy. The copper content of the liver in eclampsia was very low indeed, and the administration of copper might prevent toxæmia. Human milk was richer in copper and iron than was cow's milk; the copper content of milk could not be increased by feeding the mother with copper. These conclusions could not at present be applied to adult hæmoglobin deficiency.

Manganese was chiefly concentrated in the liver, pancreas, kidneys, and suprarenals, and was found in the blood-serum. No variations had been found in conditions of disease. The liver of the new-born had no reserve store of it; the maximum attained was the normal adult level. Meconium contained a good deal of manganese. In rats lack of manganese had caused a failure of endocrine function, particularly of the reproductive processes. It played no part in the utilisation of iron. All the common preparations of iron contained manganese as an impurity.

Dr. J. F. WILKINSON said that manganese had no value in anæmias, and in most cases his experiments had shown no benefit to accrue from copper alone. These mixed treatments owed their results to the iron; iron alone in adequate doses gave as good results as anything, and only in rare cases could success be attained by smaller doses of iron supplemented with copper. Some patients on iron showed no change for two or three months and then improved suddenly; their use as controls thus vitiated experiments.

THE LANCET

LONDON: SATURDAY, OCTOBER 1, 1932

VITAMIN-A RESERVES IN THE HUMAN LIVER

A series of four contributions to the study of vitamin A in relation to experimental animals and to man have been published in our columns during the past three weeks, the concluding one, by Dr. H. N. Green, appearing in our present issue. The ground was cleared by the convincing demonstration given by L. J. Harris and his co-workers[1] confirming conclusions already reached by others that vitamin A has no relation to the general immunising processes of the body; the mistake of attributing to it some influence over these processes is still often made, even by informed persons. The only function performed by vitamin A, which can truly be called an anti-infective one, is the maintenance of the health of the mucous epithelium throughout the body; in vitamin-A deficiency that epithelium becomes keratinised, and its efficiency as a barrier against microbic infection is impaired. This process can be well observed in the rat, particularly when the deficiency is partial so that life is maintained for some time; the relation between deficiency of vitamin A and the keratinisation of the mucous epithelium, with consequent infection, is, in this animal, indisputable. The inference that in man the same process of epithelial deterioration takes place as a result of vitamin-A deficiency, and that a degree of partial deficiency is not infrequent among human beings, is still, however, unproven. The only evidence hitherto available that the reserves of vitamin A in a human population might be too low was provided by the fact that a certain number of cases of well-marked deficiency occurred, from which it was inferred that other cases of partial deficiency must also be present. In this country 17 cases of xerophthalmia and night blindness were seen in the course of one year at the ophthalmological department of a hospital in the North of England[2]; the possibility that a partial deficiency is quite widespread among the poorest classes must therefore be accepted.

The observations made by L. K. Wolff[3] in Holland and by T. Moore[4] and Green separately in this country now provide data of a more concrete nature. These workers have investigated by means of the antimony trichloride reaction the vitamin-A content of the liver of human beings who for various reasons have come to autopsy; in the series investigated by Green all the cases were puerperal. The liver is, as far as we know, the chief storehouse of this vitamin within the body, and its vitamin-A content should give a very good index of the reserves present in it. Such human material is exceedingly difficult to classify. The great variation in the values obtained, even for seemingly comparable individuals within a group, makes it necessary to collect a very large number of results before statistically reliable conclusions can be drawn. Even the observation that great variation exists has value, however, and many other important facts have been elicited. It is noteworthy that both Wolff and Moore found the highest values in the livers of diabetics; this is due to the preponderance in their special diet of vegetables containing carotene, the precursor of vitamin A. All other values were markedly below these diabetic ones. An obvious difficulty in such work is the collection of material from normal healthy individuals in order to obtain a normal standard of values. Moore had at his disposal material from 23 cases of accident or poisoning, and Wolff had a corresponding series of 78 cases; and though the values in each series showed fairly wide variation, the average values for the two series are substantially the same, and may be regarded as a standard for comparison.

The diseases in which Moore found that the vitamin-A reserves tended to be low were organic heart disease, non-tuberculous respiratory diseases (particularly bronchitis), organic kidney diseases, septicæmias, and certain septic conditions, but in many other infective conditions the reserves were regarded as adequate. He is therefore forced to the conclusion that the vitamin cannot be regarded as a positive anti-infective agent, indiscriminate in action, but that partial vitamin-A deficiency may be a factor in the ætiology of some types of infection under clinical conditions. Wolff reckons that about sixteen per cent. of the people of the Netherlands have inadequate vitamin-A reserves, and he adds the interesting observation that these reserves tended to be unduly low in the newly born. Green found that the vitamin-A reserves were low in most puerperal cases, and that they might remain low even after large amounts of vitamin A had been administered therapeutically. He gives reasons for believing that this is not due to lack of absorption of vitamin A when taken by the mouth, or to significant loss through urinary excretion, but rather to a failure on the part of the liver cells to incorporate the vitamin when it reaches them in large quantity before it is either destroyed or passes into the general circulation. A new method of approach is being opened by this work. The preliminary findings are suggestive, though, as the authors fully realise, much more relevant material will have to be collected before conclusions of statistical significance can be drawn.

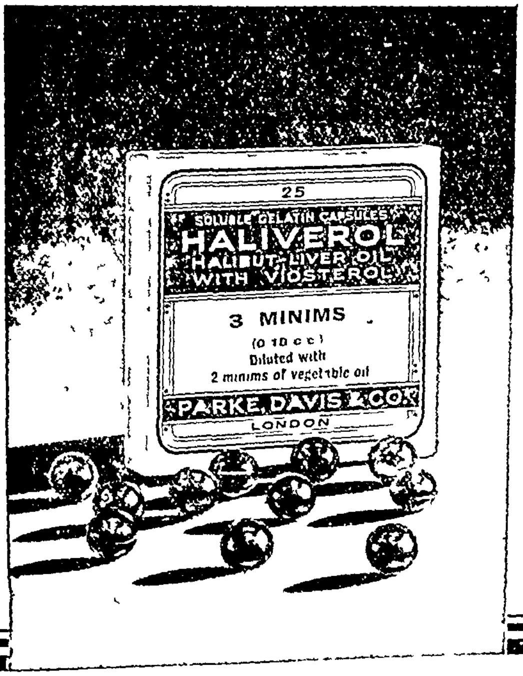
A NEW PARKE-DAVIS PRODUCT

HALIVEROL is the oil extracted by Parke, Davis & Co. from halibut livers by a special process. It contains 60 times as much vitamin A as cod-liver oil; and its vitamin D content is adjusted with irradiated ergosterol to 250 times that of cod-liver oil. Haliverol is indicated in all conditions in which cod-liver oil is prescribed, but it is taken in drops instead of teaspoonful doses.

HALIVEROL

(Halibut-Liver Oil with Viosterol)

1 minim
of
Haliverol
is equivalent
in Vitamin A & D potency
to
1 teaspoonful
of
Cod-Liver Oil



Supplied in 5 c.c. bottles, with dropper; and in boxes of 25 capsules each containing 3 minims. Further particulars will be sent on request.

PARKE, DAVIS & COMPANY
50, Beak St., London, W.1
Inc U.S.A. Liability Ltd
LABORATORIES: HOUNSLOW, MIDDLESEX

The work is essentially a plea for a wider outlook pædiatrics since, in the committee's words, nfant hygiene cannot be reduced to purely ysical terms." Even the primary factors of ding, sleeping, exercise, rest, metabolism, are rms of "behaviour" and as such find an ultimate ference in personality and infant-parent relationip. The lesson is emphasised by the curious ntrast between the discussion of the problem mothercraft in two books which have recently en submitted to us for review. To take, for ample, the sections on weaning, in one[2] e dietary is laid down in detail, and emphasis laid on the need for gradual weaning the interests both of the mother and child; it no hint is given that the general upset hich may result from a sudden change is ot solely due to the ingestion of unaccustomed od on the one side or the painful engorgeent of the breast on the other, but has a eep psychological element. Sucking its mother's east undoubtedly gives the child pleasure, quite part from the fact that the breast is a urce of food; when such contact is denied e child feels aggrieved and needs extra mothering" and affectionate attention to enable to readjust its attitude to life. The ways in which is emotional disturbance can be most easily vercome are set out sympathetically in a book esigned for mothers[3] which, however, deals purely with the psychological aspect of weaning among other stages in the relation of adult to child, the sole contribution to material considerations being advice to make the first few artificial feeds specially palatable. It is perhaps not desirable that the laywoman should be burdened with psychology and dietetics in the same book, especially as few medical authors are yet qualified to advise on both. But we do look forward to a time when a first-rate text-book on mothercraft designed for the practitioner will not deal almost solely with the physical management of the child. It is true that in Dr. JEWESBURY's book two pages are allotted to nervousness between notes on alkalosis and tetany, and that encouragement rather than scolding is advised for enuresis, but the emotional aspect of the relation between mother and child is hardly touched. According to the report quoted above, pædiatrics should include a periodic survey not only of health but of "behaviour patterns" if it is to reach an understanding of the child. The authors of the report suggest that the most fruitful line of attack for future research is to be found in extensive study of a relatively small number of children spread over a long period, rather than in the statistical study of masses. Such studies, they think, seldom contribute greatly to the understanding of the individual case. Even more important, in our view, is the teaching of the study of the mental reaction of the child to its environment as an essential part of mothercraft; the series of wireless talks, initiated by Prof. CYRIL BURT on Tuesday evening last, are likely to encourage such study.

ANNOTATIONS

NOTIFICATION OF FOOD POISONING IN LONDON

FOOD poisoning became a compulsorily notifiable disease in London by virtue of Section 7 of the London County Council (General Powers) Act which received the Royal assent last July, at the end of the session. A registered medical practitioner who suspects or becomes aware that a patient is suffering from food poisoning must forthwith notify the district medical officer of health. The notification must take the form of a certificate stating (*a*) the patient's full name, age, and sex, (*b*) the full postal address of the house or premises where the patient is, (*c*) particulars of the food poisoning, and (*d*) a statement whether the case occurs in the notifying practitioner's private practice or in his practice as medical officer of any public body or institution. Failure to notify will involve liability to a penalty not exceeding 40*s*. The practitioner is entitled to a fee for the certificate, 2*s*. 6*d*. if the case occurs in his private practice, 1*s*. otherwise. The section is slightly more elaborate than previous precedents elsewhere. Hitherto, in areas where food poisoning has been made compulsorily notifiable under local act, it has not been usual for Parliament to require notification by certificate or to insist upon more information than the mere name and address of the patient. Clauses of the usual type occur in the local Acts obtained in the current session by both Rochdale and Bury. The provision is not novel. A rapid glance through the local legislation of the post-war years reveals six instances of compulsory notification of food poisoning in the Acts of the session 1930–31, 11 in those of 1929–30, 4 in 1929, 10 in 1928, 3 in 1927, 1 in 1926 (Guildford), and 1 in 1924 (Wakefield). Presumably the search must be prolonged still further back in order to discover the local authority which has the credit of having originated the clause; presently, no doubt, the clause will find its way into a public health act applicable to the whole country. Meanwhile, its operation in the metropolitan area gives opportunity of large-scale trial. Prompt pooling of information as to food poisoning outbreaks (with particulars of their nature) will enable warnings to be circulated to medical officers who have the care of an enormous population. The clause in the recent London Act not only amplifies the information required; it also adds two further subsections. One of them enacts that if there are two or more medical officers in a district, the certificate must be sent to the officer who has charge of the area in which the patient is, or to such other of the officers as the sanitary authority may direct. The other new subsection provides that certificates may be sent to the medical officer either at his office or at his residence. In addition there is a consequential application of Section 57 of the Public Health (London) Act of 1891 to ensure that the receipt of a fee by a medical practitioner for the notification of food poisoning shall not disqualify him from membership of the county council or of a sanitary authority, or from service in any other public office.

HISTORY OF ST. THOMAS'S HOSPITAL

FROM its massive pavilions and its very special advantages of site and frontage St. Thomas's Hospital is to-day perhaps the most imposing of all the great London hospitals, and the story of its past should interest many outside its walls. Fortunately the records have been carefully preserved and the wise and public-spirited action of the treasurer and almoners in having the Hospital Chartulary translated and printed in a slightly abridged form has been followed by a book in which Prof. F. G. PARSONS describes with care and erudition the history of the hospital from the earliest times up to the year 1600.[1]

From the researches of Prof. PARSONS it would seem that St. Thomas's Hospital is a good deal older than its name suggests, and that before BECKET was murdered in 1171 the religious organisation that was to evolve into a hospital named after him cared for the sick in Southwark. The religious house in question was dedicated to St. Mary the Virgin, and was popularly known as the community of St. Mary Overei; it occupied the site of the present church of St. Saviour's, Southwark, and was staffed by Austin canons and canonesses. Prof. PARSONS believes that the infirmary of this institution from which the spital of St. Thomas grew began its work in 1106. He suggests accordingly that RAHERE must have looked carefully into the medical arrangements at St. Mary's Overei before founding St. Bartholomew's in 1123. In both institutions the canons belonged to the Augustinian order, and in both the hospital was subordinated to the Prior. It is interesting to learn that King JOHN, while he tightened this link between the Priory and Hospital of St. Bartholomew's, freed St. Thomas's from all dependence on the Priory of St. Mary. In 1212 a disastrous fire destroyed most of this Priory, and the Bishop of WINCHESTER, in appealing for funds, expressed himself as follows: "Behold, at Southwark an ancient spital built of old to entertain the poor has been entirely reduced to cinders and ashes." Prof. PARSONS tells us that the Bishop knew very well how credulous were the people to whom he was appealing, and that in order to reap an earthly harvest he must first sow heavenly seed; so he gave an indulgence of 20 days to subscribers. As a result ample funds were raised and the hospital was rebuilt on a new site over the road and now dedicated to ST. THOMAS À'BECKET. This skilful bishop was PETER DE RUPIBUS and he had served as a Knight under RICHARD I., so that here we have an early example of successful propaganda by an ex-Service man. He appears to have been one of the very few people always faithful to that much abused monarch King JOHN, and he crowned HENRY III.

Weaned in this way from the mother Priory in 1215, St. Thomas's has had an eventful history during the seven centuries that have since elapsed; the first volume of this history, crowded as it is with events and data illustrating the life of the hospital, only takes us up to 1600. The history will charm all who are interested in old medical foundations, and especially those who have received their medical education in the great hospital dedicated originally to St. Thomas the Martyr, but after the Reformation to St. Thomas the Apostle.

* * *

THE CHILD'S DEVELOPMENT

A SUMMARY of the existing knowledge of the growth and development of children, with a view to its practical application to the assessment of the normality or abnormality of individual children and to prognosis of their future possibilities has recently been issued by a Committee of the White House Conference on Child Health and Protection.[1] Both mental and physical status are considered; the former occupies twice as much space in the book as the latter, and leaves the impression that the resources available for mental assessment, although far from complete, are already not only more numerous but more useful than those on the physical side. It is, indeed, only in relation to skeletal development that anything suggesting a measured physical scale has been achieved. Medical science has been concentrated upon the abnormal and the diseased, and normal physical development has not received the attention it merits. Psychology, on the other hand, largely through the application of experimental methods, has, in a comparatively short period, attained at least an approximate idea of the normal in mental life and growth. Mental growth is here expressed in changing patterns of behaviour relating to posture, locomotion, prehension, manipulation, language, and adaptive and social behaviour. In most of these both mental and physical factors are involved. A fairly detailed account is given of the "patterns" appropriate to different ages, advancing by months in the first year and by gradually increasing periods later, and tests applicable to ages beyond infancy are fully discussed. Unfortunately, detailed knowledge of these tests is assumed of the reader, which detracts somewhat from the value of the report from the point of view of one seeking enlightenment. In spite of its title it supplies indeed rather an appraisement of materials and methods than practical help for the appraisement of any child. Chapters on the mentally superior, the mentally inferior, parental education, and sex teaching are of interest but do not provide any definitely new or original contribution to our knowledge of these subjects. The concluding section on methods of clinical examination is *probably the most valuable section of the report* especially to child welfare and school medical officers. Such examination is designed not merely to discover existing abnormality, but to search for indices of development and for preludes to the abnormal.

t would thus appear that 20 of the 84 children xamined by Dr. Morison had one (18 cases) or two 2 cases) defective parents. A reduction of 24 per ent. in the incidence of defectiveness could therefore have been effected in this series by preventing the propagation of the defective parents. The discrepancy between these two sets of findings points to the necessity of further research, and it is gratifying to note that the heredity of mental defectiveness is one of the subjects that is to be considered by the Departmental Committee recently appointed by the Minister of Health to inquire into the value of sterilisation as a preventive measure.

SUBJECTIVE SENSATIONS

It is the common experience of most to suffer at one time or another from such sensations as tingling, pins and needles, burning, or coldness. The mechanism of their production has been studied by U. Ebbecke[1] and others, and has recently been the subject of investigation by Sir Thomas Lewis and his associates.[2] Following constriction of a limb sufficient to stop circulation, tingling and allied sensations are soon felt at the periphery of the limb; gradually the parasthesiæ creep proximally towards the constricting band. If, however, at the onset of these sensations a constricting band is placed distal to the original one and the latter released, the tingling disappears. From experiments of this kind it has become evident that the tingling could not be dependent upon changes at the periphery, but must be the result of changes in the nerves underlying the constricting band; in other words, the tingling arose from changes not at the periphery but proximally at the site of constriction. H. C. Bazett and B. McGlone,[3] working on the sensations of cold and heat experienced immediately following the release of constriction, have brought forward evidence favouring their production by biochemical products elaborated during stasis of the blood. With sensitive thermocouples buried in the skin at varying levels, they determined the actual temperature of the tissues during the conscious feeling of cold and heat as above produced. Release of the blood flow with the arm bathed in water at body temperature gave rise to marked sensations of heat, but caused no alteration of temperature in the tissues of sufficient magnitude to account for the sensation experienced. These experiments, elaborated in various ways, led Bazett and McGlone to the deduction that the sensations were dependent upon the action of some biochemical factor upon the temperature nerve-endings. Alteration of the temperature of the arm and of the duration of constriction caused variation in the intensity and character of the sensations, and it appeared that the sensation was roughly associated with the probable acidity of the blood flowing into the dermal area previously rendered stagnant. Further weight is added to this deduction by the demonstration of the greater intensity of the sensations following stasis in the arm than of those following stasis limited to a finger; this observation is regarded as favouring the production of a chemical substance derived from the metabolic processes in muscle tissue during stasis. In this way the work becomes closely linked with that of Lewis upon the pain associated with intermittent claudication. Of great interest is the evidence, produced by various observers, that the sensation of pain, heat, and cold may be separately produced by chemical factors; whether there is a chemical link between stimulation of the normal skin and impulses arising in the sensory nerve-endings remains a problem of the future.

THE DEVONSHIRE COLIC

In 1617 Citois claimed that bad wine which had been treated with lead was a cause of colic among the Pictones or inhabitants of Poictou. This colica Pictonum he described excellently, but he attributed the disturbance chiefly to the acid of the wine. Late in the seventeenth century colic and paralysis following the addition of litharge to wine became notorious. Indeed, in 1696, the Duke of Würtemberg was so impressed with the danger of this practice that he issued a decree making it a capital crime. About this time colic became prevalent among cider-drinkers in Devonshire, but it was many years before lead was proved to be the cause. In 1703 Musgrave stated that the colic in Devonshire, sometimes associated with paralysis, was caused by the excessive use of crude cider which was too acid. Huxham, in 1752, described the colicky pains and paralysis in vivid fashion. He expressed his conviction that the Devonshire colic was due to the tartar extracted from the apples in the process of making cider. It was Sir George Baker, himself a Devonshire man, who first followed up the analogy between lead colic and the Devonshire colic (1767). He finally proved his point conclusively by demonstrating that the cider of Devonshire contained lead, while that of Herefordshire did not. He showed, further, that in Devonshire, but not in Herefordshire, it was a common practice to line the cider presses with lead. He also exposed the practice of adding metallic lead, litharge, or lead acetate for the purpose of correcting sour cider. His investigations created a great storm, and he was denounced as a traitor to his county. Although colic due to the employment of lead in the manufacture and storage of cider has now disappeared, minor outbreaks of plumbism due to cider-drinking still occur from time to time. It is of interest that Dr. and Mrs. L. N. Jackson should have discovered that lead colic is still endemic in Devonshire amongst cider-drinkers, though from a different cause. In a paper in our present issue they describe ten patients with lead colic, frequenting eleven public-houses in a Devonshire town. In six of these houses they found lead in the cider as drawn by the bar engine, though samples from the cask were in all cases free from lead. In these days when public-houses are subjected to so many restrictions, designed to protect the public, it is curious that they should be allowed to continue to use lead pipes to convey cider or beer from cask to bar engine.

THE PREVENTION OF POST-VACCINAL ENCEPHALITIS

In the absence of precise knowledge of the ætiology of post-vaccinal encephalitis any suggestion as to its prevention, however slenderly based, is worthy of notice. The observation made by the New York Poliomyelitis Commission, 1916—that among 954 poliomyelitis patients, 1 to 4 years of age, the attack-rate among the Schick-positive was six to seven times as high as among the Schick-negative children—has recently been recalled in another connexion. In a recent issue[1] of the public health reports of the U. S.

URINARY TRACT CHANGES IN PREGNANCY AND PUERPERIUM

NUMEROUS recent studies have demonstrated the anatomical changes which normally and abnormally occur in the urinary tract in pregnancy and the puerperium. Most of these examinations were carried out on post-mortem material or on the living subject by means of retrograde pyelography. The more recent introduction of intravenous pyelography has opened up a new method of approach to a difficult subject. William F. Mengert and Harry P. Lee[1] have lately used the method on 41 pregnant women, 20 primiparæ and 21 multiparæ. In order to establish an index of the amount and frequency of urinary tract dilatations, and as a basis for judging postpartum changes, the first radiograms were made during late pregnancy, and further exposures, usually three or four, were obtained during the fortnight following delivery. Stereoradiograms were taken in all cases, lest a single film, if it happened to be taken during a peristaltic contraction, might not represent the true size of the ureter. The antepartum pictures were taken from 1 to 65 days before the onset of labour. In all the primiparæ dilatation of some degree was present on the right side in calyces, pelvis, and ureter; on the left side it was found in about 90 per cent. of the cases. Dilatation of marked degree was three or four times as frequent on the right side as on the left, and it was encountered more often in primiparæ than in multiparæ. As to postpartum involution of the urinary tract, in eight cases a marked reduction in the extent of the dilatation was observed within 24 hours, while in 9 to 11 days after delivery all dilatation had disappeared in the majority of the normal patients examined. The involution of the urinary tract was, on the whole, slower in primiparæ; and was noticeably slower, too, in the presence of infection. It is suggested that this delayed involution may be a factor in the development of postpartum pyelitis. This assumption is not unreasonable in view of the important part played by dilatation of the ureter in predisposing a patient to antepartum pyelitis. It is probably true that antepartum pyelitis would never occur if the ureters were normal. Why they should become so often dilated during pregnancy is still a controversial question, and even more perhaps why the dilatation should be more frequent on the right side than on the left.

STREET MARKETS

IN the wide spaces of the country town market day with its bustle and spirit of holiday is a pleasant sight; in the narrow crowded streets of the metropolis certain disadvantages intrude upon the notice. The street markets of the East End have been likened to Oriental bazaars where the merchants expose for sale in the open anything from carpets to dates and drinking water. Councillor C. Bennett, at the recent Belfast Congress of the Royal Institute of Public Health, described the Bethnal Green Sunday morning "junk" market as providing a feast of horrors for the conscientious sanitarian. Old mattresses and furniture are interspersed with second-hand (or worse) clothing; boot stalls are side by side with barrows where apple fritters are being cooked in the open; slices of tinned pineapple, cakes, sweets, even sliced melon and cut oranges are exposed for sale alongside old hot-water bottles and gum boots. In one of the markets live-stock such as pigeons, canaries, geese, rabbits, guinea-pigs, and tortoise are sold side by side with foodstuffs. The traders pay little attention to the disposal of the refuse; at the end of the day shells, fish scales, feathers, decayed oranges, cabbage leaves, and wilted flowers are scattered over the roadway, eluding the provision by the borough council of receptacles for their storage. Nutrient agar plates exposed in several street markets grew colon bacilli and coarse streptococci of the salivarius and fæcalis types in addition to the moulds and saprophytes of quieter streets. Remedies are hard to apply in the face of the conservatism of Bethnal Green people. The vested interests of the market monopolies unfortunately prevented the use of Columbia market for the purpose for which the late Baroness Burdett-Coutts, with tremendous generosity, intended it. Councillor Bennett suggests that the stalls selling the more easily contaminated foodstuffs should be placed on a special site. Certainly every stall in the markets should be screened, and any on which foodstuffs are exposed should be completely enclosed, however much this may conflict with the conservatism of the public and with the wishes of the traders themselves.

THE CHILDREN OF MENTAL DEFECTIVES

SPECIFIC information about the mental state of families of mentally defectives is timely. The figures given in the annual report of the special school after-care subcommittee of Birmingham concerning the offspring of ex-pupils of the special schools are as follows: 1183 children were born into 602 families. In 312 of these families the father was an ex-pupil and in 290 the mother, the latter group including 38 illegitimate children born to defective mothers; 101 of the children are dead and many are under 5 years of age and thus did not come under observation; of the 494 children over 5 years old who had one defective parent 16 are definitely mentally defective—i.e., 3·24 per cent. This figure, however, certainly under estimates the true proportion of defective children, since systematic examinations for the admission of children to special schools do not begin until the ages of 7 or 8. It would be valuable to ascertain the number of children above 8 years of age, and also the number who are not attending elementary schools. But even if every allowance is made for cases not ascertained, it seems improbable that the numbers would be swelled to as much as double the figures given, and if this should prove to be a fair deduction the proportion of mentally defective children in this group would not exceed 5 per cent. This does not, of course, preclude the possibility that some of the children may be "carriers" of defect, and that a larger proportion of the grandchildren of the ex-pupils would be defective. But as far as they go the figures from Birmingham suggest that the prevention of propagation by defectives would not seriously reduce the number of the mentally defective in the next generation. The subcommittee hold that the evidence so far collected tends to disprove the popular idea that the mentally defective are abnormally prolific. A very different picture however is given by Dr. A. G. Morison in a study of 84 mental defectives published in our issue of Sept. 10th (p. 589). Of these children 23 belong to lower grades and 61 to higher grades of defectiveness. Of the 23 lower-grade children 5 had parents, one of whom was feeble-minded; of the 61 higher-grade children 15 had parents, one or both of whom were feeble-minded.

lmost unnecessary to add that such measures cannot eplace careful neurological examination, and should e used only in difficult cases and by men experienced n the technique.

THE MEIBOMIAN DUCTS

THE small operation for incision and evacuation of a chalazion is, as a rule, a simple matter, but occasionally, when they are multiple or become inflamed, or when they are recurrent, as they frequently are, they may become a very tiresome infliction, involving the necessity of several minor operations or causing an acute conjunctivitis which, in a severe case, may even simulate acute trachoma. The best way of handling these cases—and what is of even greater importance, of preventing their occurrence—is clearly stated in an article by Dr. Arthur Eppenstein, of Berlin,[1] which, since the method of prophylaxis is easy, should specially appeal to the general practitioner. The openings of the Meibomian glands appear normally as minute depressions in the margin of the upper eyelid, and the normal secretion is a tiny clear drop. Excessive secretion indicates the beginning of something wrong, and if it is mucoid or muco-purulent, or if a yellowish-white substance such as is seen in seborrhœa of the scalp is deposited at the openings of the ducts on the lid margin, the indication is to evacuate the duct, not by means of an incision but by pressure, applied preferably by means of a small glass rod inside the lid and a finger-nail outside which must follow the line of the duct from fornix to lid margin. This may have to be repeated several times, but if the ducts can be kept clear by this means it will probably prevent the more annoying complications from developing. Not only will this procedure be found useful in cases of recurring chalazion, but many cases of chronic conjunctivitis and blepharitis, obstinate to ordinary treatment, will rapidly improve when attention is directed to Meibomian ducts. For the operating surgeon, too, as Dr. Eppenstein remarks, it is of importance when preparing the lids before an intra-ocular incision, not to forget that the Meibomian ducts may be just as dangerous a source of infection as the lacrymal sac.

AMBULANT PHRENICECTOMY

AVULSION of the phrenic nerve to immobilise the diaphragm has been recommended chiefly as a supplement to artificial pneumothorax and thoracoplastic operations. The thesis that it may be an independent substitute for an artificial pneumothorax is presented in *Acta Medica Scandinavica* (vol. lxxviii., fasc. ii., 1932) by Dr. N. Oekonomopoulo of Athens. With an experience of 160 cases of pulmonary tuberculosis, treated by phrenic avulsion under ambulant conditions, he answers in the affirmative his own question: Can the artificial paralysis of the diaphragm be justifiably regarded as an independent operation in the treatment of pulmonary tuberculosis? He has kept 125 patients under continuous clinical and radiological control for periods up to four years; among them there were 33 who improved, and 40 who achieved a clinical recovery. Many of these 73 patients, who benefited from phrenic avulsion, had previously spent months and even years in seeking health by such conservative means as sanatorium treatment. Among the 125 were 71 in whom an artificial pneumothorax might have been induced; improvement was achieved in 19 of these cases and clinical recovery in 31—a result which Dr. Oekonomopoulo suggests would compare favourably with those which an artificial pneumothorax might have yielded. In his choice of subjects suitable for one or other operation, he tends to allot the comparatively early and limited lesions to phrenic avulsion, and the more serious cases to an artificial pneumothorax. Cases of *Fruhinfiltrat*, for example, he regards as suitable for phrenic avulsion, the effects of which are prompt, whereas an artificial pneumothorax, which is also justifiable in such cases, must be maintained for 6 to 12 months. In our present issue (p. 767) Mr. L. O'Shaughnessy describes his experience when working in the Sudan of 58 cases of pulmonary disease, for the most part tubercle, treated by phrenicectomy, which the primitive conditions led him to prefer to other forms of collapse therapy. The material was in no way selected, as even in the worst cases he hoped to obtain for the patient some relief of symptoms. The results as a whole, he says, were not encouraging, although in several cases there was a restoration to normal health for a year or more before the inevitable relapse. Mr. O'Shaughnessy suggests that the chief value of phrenicectomy as an individual measure may be found in cases whose balance has just not been tilted towards health by the ordinary methods of rest and diet. It may have a subsidiary function in the relief of symptoms caused by adhesions in the region of the diaphragm. Though phrenic avulsion requires considerable surgical skill, it is yet a simple operation, entailing little risk of immediate or late complications. An operation which requires no prolonged institutional treatment has, of course, a distinct advantage over one that implies months of residence in a hospital or sanatorium; and this has particular point in communities with a high tuberculosis-rate and little institutional accommodation.

THE RULES OF DEATH CERTIFICATION

A MONTH or two ago we published a letter[1] criticising the rules drawn up by the Registrar-General for primary tabulation when joint causes of death are stated on the certificate and we were then in a position to assure our readers that it is the definite policy of the General Register Office to rely upon the information of the certificate rather than upon arbitrary rules, the hindrance to giving effect to this policy being the failure of the medical profession so far to make extended use of the new form of death certificate, a form expressly designed to make it easier for the certifying practitioner to provide the Registrar-General with the information he needs. In our correspondence columns this week Dr. G. Sowden, medical officer of health for St. Pancras, expresses a doubt if the desirable practice mentioned in our leading article of August 20th (p. 405) is really adopted by the General Register Office. "In my experience," he writes, "I have found that the application of the rule of selection is invariably followed, and any disease in a lower group is preferred to one in a higher, notwithstanding the opinion of the certifying practitioner," and he cites an instance in which he was informed by the Registrar-General that the cause of death was to be classified to tuberculosis, although the immediate cause was certified as diabetic coma. The certifying practitioner, it seems, stated that tuberculosis was discovered owing to a post-mortem examination, and that the

[1] THE LANCET, August 20th, p. 419.

Treasury Department, Dr. Charles Armstrong summarises what is known of post-vaccinal encephalitis and its prevention, and suggests that collateral immunity against other diseases may carry with it a certain resistance to this grave, if very rare, complication of vaccinia. Certain experiments were devised to test the hypothesis, using a strain of vaccinia developed some years ago by Rosenau and Andervont, which produced a fatal meningo-encephalitis when injected intracerebrally into white mice. A dose of this virus was selected which was slightly less than that sufficient to kill all of a group of normal mice, and the effect of this dose was compared on groups of normal mice and in mice which had been previously immunised with diphtheria toxoid. At the end of 25 days the survivals in the normal group were 12 per cent., while in the immunised group they were 27 per cent. Previous immunisation to diphtheria toxoid thus appeared to turn the scales against the incidence of cerebral complications occurring in mice. Dr. Armstrong admits that the protection of a few mice from a cerebral virus infection by means of a previous non-specific stimulation of the defence mechanism does not necessarily lead to the conclusion that children could be similarly protected from post-vaccinal encephalitis, but in the absence of any other method of protection the suggestion arising from Dr. Armstrong's experiments might be followed up. He proposes that primary vaccinations, especially after the first year of life, should be deferred until immunisation against diphtheria or other diseases by means of inanimate antigens has been accomplished. Such a definite recommendation coming from a highly expert official is worth considering by those who have to face a delicate problem in administrative hygiene. Immunologists rightly hold fast to the strictly specific view of immunity upon which all that is most solid in their science is based, but " practice makes perfect " is a biological law of wide application, and it may well be that a preliminary exercise with one antigen somehow teaches the organism how to deal with others far removed in the scale of specificity.

THE BRIGHTER SIDE OF EPILEPSY

It is common knowledge that there are more epileptics outside institutions than inside, and that much, if not most, of the published work on epilepsy has been done in institutions. Epilepsy, in this respect, shares the lot of other diseases in that the clinical and scientific aspect of the serious cases which get inside hospital wards or institutions tends to become the text-book picture, often with a darker outlook than would be given by the experienced general practitioner. Naturally, it is the milder cases, with few fits and little mental deterioration or abnormality, which are found outside institutions, and of these Dr. H. A. Paskind, of Chicago,[1] gives a more hopeful outlook than that generally held. His paper is a study of the after-history of 304 epileptics who had had the disease for six years or more, many of them having suffered for periods up to 20, 30, or 40 years, or even longer. In this survey only 20 patients, or 6·5 per cent., were found to have deteriorated mentally, the whole of the remaining 93·5 per cent. being in excellent mental health, without the slightest trace of deterioration or other psychosis, and engaged in occupations similar to those of the great mass of the population. Such few cases of deterioration as were found were not more frequent among those who had the disease for a very long time. Dr. Paskind compares these extramural cases of epilepsy, as he terms them, with institutional patients, and finds, as one would expect, that his cases have very much fewer attacks, both of major and minor type, and that periods of freedom from fits are more frequent and last longer. The age of onset was on the average markedly later, about a third of the cases not having their first fit until after their twenty-fifth birthday. Among the families of the extramural patients, epilepsy, psychoses, alcoholism, and other manifestations of the neuropathic heredity, except migraine and so-called nervousness, were far less common than among those of institutional patients. It would require other surveys of records in private practice before Dr. Paskind's picture can be taken as typical; but it should at least encourage those who have epileptics under their care to combat the lack of incentive and of competition that induces the progressive narrowing of mental horizon generally considered typical of epilepsy.

LOCALISATION OF CEREBRAL TUMOURS

It is disappointing that increased knowledge of the physiology of the central nervous system has as yet brought little help in the localisation of cerebral tumours. Neurologists and neuro-surgeons continue to find regional diagnosis very difficult. The introduction of ventriculography by W. E. Dandy some years ago appeared to offer hope of a considerable advance in accuracy. The value of this technique has recently been assessed by A. W. Adson[1] and F. C. Grant,[2] who have published separately the results of an extensive trial of this method. Both have used two procedures, (1) direct filling of the ventricles with air, and (2) the replacement of the cerebrospinal fluid with air via the lumbar route; this method permits air to pass not only into the ventricle but also over the surface of the brain. Following direct ventriculography, a study of the X ray appearances of the outline of the ventricles in varying positions of the head frequently offers help. The internal hydrocephalus associated with tumours situated in the posterior fossa, the distortion of one or both anterior horns associated with frontal tumours, and the alteration in the outline of the lateral ventricles associated with temporal lobe tumours are well recognised. But the real value of this technique can be assessed only by a consideration of the results obtained in tumours not localisable after a careful neurological examination. Adson found that this method gave positive localising evidence in 23 per cent. of cases not localised clinically; Grant found it successful in 21 out of 48 cases without localising signs. Both observers have thus been able to reduce the number of cases in which they would have hesitated to operate. On the other hand, the technique is by no means safe; fatalities are recorded averaging about 6 per cent. This percentage must of course be considered with due regard to the bad prognosis in cerebral tumours which cannot be located for operation. Encephalography, a simpler procedure than direct ventriculography, is also less useful; it is contra-indicated in cases of increased intracranial pressure, especially in tumours situated in the posterior fossa. It may, however, give help in the differential diagnosis of varying conditions involving the cortex, such as cortical atrophy, traumatic lesions, and vascular disturbances. It is

POST-GRADUATE LECTURES

At the beginning of this winter session lectures nd demonstrations to old students and other raduates are again being given at many of the London eaching hospitals. The following are summaries of hree lectures delivered at Westminster Hospital in a ourse, held under the auspices of the Fellowship of Medicine.

THE INOPERABLE CANCER PATIENT

(MR. STANFORD CADE)

Of all cases of cancer seen in hospital only 20 per cent. are operable.[1] If this statement is correct it means that 80 per cent. of cancer patients when first seen are incurable by surgery. If one adds to their number the cases of post-operative recurrence—by no means a small proportion—it becomes obvious that the problem presented by this group of patients is as great as it is depressing.

It is to be hoped that a time will come when to-day's means of alleviation and treatment will all be measures of the past, swept into oblivion by some specific medicinal remedy. In the meantime what have we to offer to the non-operable patient? Above all, an attitude of helplessness and hopelessness, not infrequently adopted by both doctor and relatives, must be condemned. Certain therapeutic procedures, whether curative or palliative, should receive due attention, since they can without doubt increase the patient's happiness and comfort.

Physical agents.—So long as the action of radium and X rays on living cells is not understood, treatment by radiation remains empirical. If to this is added the fact that measurement of the quantities of energy received by the tissues presents the greatest difficulty, it is not surprising that radiation therapy has so far undergone successive periods of unjustifiable enthusiasm and depression. Nevertheless, as used by experts in institutions where team-work is understood and practised, X rays and radium have to-day no rivals in the treatment of malignant disease. The choice between them, or the combination of methods, depends upon the type of cancer, its situation and extent, and upon the general condition of the patient. The results to be expected can be summarised as follows:—

In inoperable carcinoma of the *uterus* arrest of hæmorrhage, diminution of discharge, and healing of ulceration, are usually obtained for periods varying from a few months to five to ten years or more in cases of apparent cure. The methods of irradiation by radium, X rays, or by combined treatment are simple and present no great technical difficulty or risk. For inoperable cancer of the *mouth* and *tongue*, my own figures, based upon 350 cases, show five-year survival in 11 per cent., healing of primary lesion in 85 per cent., local recurrence in 20 per cent. For periods varying from one to three years the disease appears arrested, healing occurs, and there is an amount of palliation which can only be fully appreciated if one is in constant touch with the patients. No lesion in the mouth is too advanced to be relieved in some measure by careful radiation. Death as a rule is caused by invasion of the lymphatics. Post-radiation pain, sepsis, neuritis, and necrosis can be avoided by accurate treatment, efficient screenage, and appreciation of the dose to be given. In inoperable carcinoma of the *breast* temporary retrogression of the disease and healing of ulceration takes place in 70 per cent. of cases. Death is usually the result of visceral metastasis, with a minimum of external evidence of the disease. In cancer of the *rectum* and *œsophagus*, however, treatment by radiation offers very little and can be considered purely experimental.

Daily observation of patients during the past eight years has convinced me that by physical agents palliation is obtained in the vast majority of cases, that such palliation is well worth offering to the patient, that apparent restoration to health and return to normal occupation is more commonly seen than is generally believed possible. The following few cases will serve to illustrate the palliative results of radiation treatment.

(*a*) Carcinoma of both breasts, numerous cutaneous ulcerative lesions, and wide lymphatic dissemination, in a patient aged 50. Radiation has enabled her to resume her occupation as a saleswoman with a firm of surgical instrument-makers. I have no doubt that many a surgeon, sceptical as to the value of radiation, has been served by this patient.

(*b*) Extensive local recurrence following perineal excision of the rectum. This patient was treated with radium in 1928, and sufficient palliation was obtained to enable him to travel to India every year and follow his occupation.

(*c*) Inoperable carcinoma of the tongue, with secondary deposits in the cervical glands. Radium has produced complete retrogression of the disease, enabling the patient to follow his occupation as solicitor's clerk for the past six years.

As no surgical acumen or clinical experience can forecast the result of radiation treatment, it is always to the benefit of the patient to receive such treatment.

Chemical agents.—It would be simpler to enumerate the metallic substances which have *not* been tried at some time or another in the treatment of malignant disease than to give a list of the metals which are supposed to have cancerocidal properties. Arsenic, bismuth, gold, lead, selenium, and uranium have had the longest trial. Of them all there is only *one* substance which need claim our attention, *lead selenide*, as introduced by A. T. Todd of Bristol. It is free from the slightest hint of "patent medicine," is obtainable at a very small cost, and can be given with safety by the patient's private doctor. In small doses (1 to 3 c.cm.) it definitely relieves pain and diminishes cachexia. In a few undoubted cases it has led to marked retrogression of the disease for periods of a few months to two years.

Biochemical agents.—Adrenaline, pituitrin, theelin, and some sera have all from time to time received publicity as cancer remedies. Recently an extract of parathyroid gland has been endowed with similar qualities. No confirmation of the original work is yet forthcoming. These substances need not claim the clinician's attention; they are so far of interest only in laboratory experiments. No doubt some have growth-restraining properties, but it is unfortunate that "growth" and "tumour formation" should be considered as synonymous.

Non-specific medicinal treatment.—In the treatment of the inoperable cancer patient much can be done in addition to radiation therapy by the following means:—(*a*) Blood transfusion is valuable as a preradiation measure if the blood count shows a fall of red cells to under 3,000,000. (*b*) General heliotherapy, with the exception of the affected area. (*c*) Administration of iron, calcium, vitamins, and liver extract. (*d*) Small doses of cocaine are occasionally immediate cause of death was diabetic coma. Dr. Sowden regarded that statement as indicating in the mind of the practitioner that tuberculosis had little if anything to do with the death and was only ascertained incidentally; it certainly was not the morbid condition which gave rise to the diabetic coma, and yet, he complains, tuberculosis is the cause selected by the rules of the General Register Office. To put it another way, if the post-mortem examination had not been made, the practitioner would probably have certified "Diabetic coma—Diabetes," and the cause would have been accurately recorded. We gladly publish Dr. Sowden's letter because it reveals a difficulty, which seems to be widely felt, of interpreting the present form of the death certificate and the annotations accompanying it. If attention is paid to the form of this certificate it must however be clear that, if the practitioner assigns diabetic coma as the immediate cause of death, the death would not be tabulated to diabetic coma, because "immediate" is specifically stated to be immediate in point of time. The Registrar-General might say very justly: "If you look at the official form you will see that the practitioner certified that the immediate cause of death was diabetic coma *due to* pulmonary tuberculosis. In other words, he certified that the real cause of death was the tuberculosis, although it reached its fatal termination by the instrumentality of the diabetic condition. By his certificate he made it clear that the immediate cause in his opinion was not the causa causans but merely an intermediate link in the chain between the real antecedent cause of tuberculosis and the death itself." The General Register Office has put up a hard fight to keep out of certificates "causes" which are merely terminal modes of exit; it does not want to classify by subordinate links in the chain of causation from the real cause to its fatal outcome. In cases where a long chain of antecedent causation is certified, some question might arise as to where the chain is to be cut for the purposes of classification; but no such question arises here. Had the practitioner intended to signify that the two causes were of independent origin and that the tuberculosis had merely a contributory and collateral bearing upon a death ensuing from the diabetic condition or its direct consequences, he would (or should) have used paragraph II. on the form.

AN ENDOWMENT OF CLINICAL RESEARCH

THE Rockefeller Foundation has handed over to University College Hospital, London, the sum of £48,800 "to constitute a fund for the permanent endowment of a post, the holder of which will devote his whole energies to the advancement of clinical research." The gift is made with a view to encouraging the progress of clinical research on lines which the Medical Research Council has been developing in conjunction with University College Hospital Medical School since 1916. The idea underlying the scheme is that there should be brought into existence a body of workers, free from ordinary hospital routine and teaching, who would devote their whole time to the investigation of special clinical problems. Since 1916 the Medical Research Council has financed such a body of workers under the guidance of Sir Thomas Lewis at University College Hospital, and in 1930 the hospital formally recognised this group as a definite Department of Clinical Research. It is thus fitting that the post endowed should be the one at present held by Sir Thomas Lewis as physician-in-charge of this department. This magnificent gift will release sufficient funds to enable the Medical Research Council to make provision for further po of the same nature, and so to give younger worke the possible prospect of a life devoted to the scientific study of clinical problems unhindered by the distractions of consulting practice or by the distance from human patients which posts in [illegible] enforce. The establishment [illegible] research should help to resolve the divergence of outlook between laboratory and clinical workers which is clearly demonstrated in the discussion reported on p. 740, and bring about the closer alliance between medicine and other branches of science which Dr. Hutchison noted as one of the great needs of the day. The Rockefeller gift is entirely educational in scope and will in no way relieve any hospital thus endowed of the burden of raising funds for charitable purposes.

FAMILY PREDISPOSITION TO URINARY CALCULI

VERY little has been recorded about the heredity factor in the formation of calculi. The French, it is true, have created the term "diathèse oxalurique," but the appearance of oxalic acid crystals in the urine does not necessarily imply, although it may favour, the formation of calculi. Dr. H. C. Gram belongs to a family in which a predisposition to calculus formation seems to exist, and has recently published[1] the results of a study on oxalic urinary calculi from the point of view of heredity. In members of five generations observed there occurred with great frequency stones which were found on analysis to consist of oxalate of calcium. The trouble was noted only in males; this is in harmony with R. McCarrison's report on 34,325 Indian cases of calculus, in which the ratio of male cases to female was as 13·2 to 1. It is not easy to find an explanation for this high relative incidence of calculi amongst males. The long urethra and the common occurrence of prostatic obstruction amongst the elderly may suffice to explain the greater frequency of vesical calculi in men, but can have no bearing on the higher proportion of renal calculus amongst younger men. As regards the heredity factor, Dr. Gram admits that his investigation concerns only one family, and does not prove that stone formation always shows a hereditary disposition; but it confirms the general impression that a tendency to calculi, as to gout, may be a familial characteristic.

THE Royal College of Physicians of London will commemorate its benefactors on Tuesday, Oct. 18th, when the Harveian Oration on the Debt of Preventive Medicine to Harvey and to the College will be delivered by Sir George Newman at 4 P.M. The commemoration dinner will be held in the College on the same evening, and the annual sermon, re-established under the scheme of the Charity Commissioners for the administration of the Sadleir Trust, will be preached at the Mercers' Chapel, Ironmonger-lane, Cheapside, at noon on Oct. 18th, being St. Luke's Day.

ON Thursday next, Oct. 6th, at 3.30 P.M., a memorial to the late Sir Andrew Balfour will be unveiled at the London School of Hygiene and Tropical Medicine by the Earl of Athlone, Chancellor of the University of London.

Summer Time, which commenced in Great Britain, Ireland, the Channel Islands, and the Isle of Man on Sunday, April 17th, will cease on Sunday next, Oct. 2nd, at 3 A.M., when the clock will be put back to 2 A.M. The hour 2–3 A.M. Summer Time will thus be followed by the hour 2–3 A.M. Greenwich time.

---

[1] Acta Med. Scandinavica, 1932, lxxviii., 268.

DIVERTICULITIS

(MR. ROCK CARLING)

DIVERTICULA are pouches of mucous membrane hich protrude through the muscular coat of the olon, especially in the sigmoid region. They occur etween the mesenteric attachment and the lateral ongitudinal bands, sometimes into the appendices piploicæ, and sometimes through the points of ntrance or emergence of vessels, and perhaps occaionally at unparticularised spots. They carry with hem little or none of the muscular tissue; they tend o expand when the muscular coat has been passed, hus becoming flask-shaped; and they rarely attain greater size than that of a black-currant or a very mall cherry. Bowel contents (including the material of an opaque enema) enter them freely and escape with little delay; sometimes so easily that they may fail to reveal themselves on a film. There may be but one or two—there may be dozens; and though by far most common in the sigmoid region, they may be found distributed throughout the colon and even in the cæcum.

Many single diverticula are certainly congenital, and the multiple form has been observed in embryos. The mere existence of diverticula does not necessarily involve any ill-health, any more than does the existence of a vermiform appendix. The pathology of diverticulitis is very like that of appendicitis. So long as the normal contents are free to escape there is no trouble, but if the contents be abnormal or too long retained, or the virulence of the bacteria be enhanced, organisms invade the tissues. The result may be mere catarrhal swelling of the mucosa, with further obstruction; or an abscess may form and burst inwards, leaving an ulcer; or burst outwards, leading to peritonitis. Even if no gross abscess is formed, adhesive inflammation may lead to attachment of the sigmoid to the bladder, or to other parts of the intestinal tract, or to the uterus and adnexa. Again, it may produce widespread cellular infiltration of the bowel wall, the formation of granulation tissue and, in due course, the proliferation of fibrous tissue and fat, with formation of a considerable tumour; finally resulting in a fibrous stricture, narrow and string-like or extensive and tubular. In many cases there are copious deposits of fat in the appendices, the subperitoneal space, and the mesentery. The inflamed diverticulum, when eroded, may lead to long fistulous tracks, winding towards the serous surface. Apart from narrowing, the general mucosa of the affected part of the bowel is not often abnormal; ulceration, local mucous or membranous catarrh are alike exceptional.

Some of the symptoms—such as abdominal discomfort, flatulence, and change of habit as to stools—attract little attention because they are common in both sexes as age advances, and are usually present round about the sixtieth year. Pain may be constant, or frequently recurrent, the intervals varying from a few days to many months. It usually occurs in the left flank, left side of the abdomen, or more widely on the left side from below the axilla to well down the thigh. Exceptionally, the pain may be right-sided, or suprapubic or vaguely "pelvic." It may accompany or follow evacuation of the bowels, perhaps with tenesmus. Cystitis may be the outstanding feature. Fever is slight, except in cases of abscess. Neither loss of weight nor loss of appetite is conspicuous. The secondary anæmia has no special features. When perforation peritonitis or intestinal obstruction occur it is without precise indication of diverticular origin.

Tenderness in the left iliac fossa is the predominant clinical sign, and it is often possible to feel the lowest part of the descending and sigmoid colon as a tender, tense, tubular mass, having the appropriate lie and course. The stools may be normal, or of late smaller than usual; neither blood nor mucus is constantly present and never in great amount; neither diarrhœa nor constipation is a regular feature, and rarely is either conspicuous. The passage of gas per urethram suggests a fistula of diverticular rather than of neoplastic origin.

Upon suspicion radiograms after opaque enema should be taken, not only antero-posteriorly but also with more than one axis of obliquity; not only with the bowel filling and filled, but also emptying and emptied, this last especially, since it may be only when the main barium mass has passed that the still-full diverticula throw clearly defined shadows.

The mildest cases should be treated by paraffin, lavage, and atropine. Graver cases call for colostomy, which should be kept open for three, six, or more months. Radiograms indicate progress and suggest the time for closure. It is probable that any considerable mass will result in narrowing, and some masses cannot be distinguished from cancer. When in doubt, resection is indicated. If this be impossible, an exclusion operation is sometimes practicable.

When intestinal obstruction is due to a band or loop adherent to the sigmoid, it should be remembered that the point of attachment may be concealing the orifice of a diverticular sinus. Vesical fistula can be successfully dealt with after a colostomy. Some diverticula, especially in the cæcal region, can be invaginated or excised.

Differential diagnosis is difficult. In colitis, the amount of mucus passed is much greater; diarrhœa is more severe and constipation more capricious—blood and membrane are likely to be passed freely. The extent of the tenderness is distributed much more uniformly round the colon, and the temperature is not infrequently subnormal. In cases of stricture there is a history of dysentery—or of perimetritis or of proctitis—or it may be evidence of past syphilis. Fæcal accumulation is more likely and more obvious. In adenoma with chronic partial intussusception there is sharp hæmorrhage, and the sigmoidoscope may give positive evidence. The real difficulty arises with cancer of the colon. The duration of symptoms is in general shorter; blood and mucus of some amount are more constant; diarrhœa may be troublesome, and the stools fœtid; distension of the abdomen is slowly and steadily, though insidiously, progressive; while loss of weight may be obvious and loss of appetite pronounced. There is, I think, much less tenderness, less pain, and less spasm. Absence of fever is just worth noting.

An error will be less likely if the alternative diagnosis of diverticulitis be remembered, and investigation be rigorously pursued until the point is settled.

MARY STEVENS MATERNITY HOME, OLDSWINFORD. Sir Hilton Young, the Minister of Health, last week opened the Mary Stevens Maternity Home at Oldswinford, Stourbridge, which has been given by Mr. Ernest Stevens, of Prescot House, Stourbridge, in memory of his wife. The building is the property of the Stourbridge town council which has leased it to the Worcestershire county council which has set up a committee to administer it. The cost of maintenance for the first year will be defrayed by Mr. Stevens. There are 15 beds, and the building stands in the park-like surroundings of White Hall, on the site of which it has been built.

of great benefit. (*c*) Abstention from morphia for as long as possible. Relief of pain can be obtained by a host of non-opium preparations which are preferable and which enable the patient to carry on his occupation.

In conclusion, it must be always kept in mind that in treating inoperable patients, the clinician must abstain from remedies which are "heroic" in nature. The *mortality* of the disease must not blind us to the mortality of the treatment. The inoperable cancer patient has a right to have his life prolonged, and this must be achieved at less price than that paid by numerous "operable" patients who stake all and lose all in the surgical act.

INJURIES OF THE ELBOW-JOINT

(MR. E. P. BROCKMAN)

THERE are certain principles which must be followed in the treatment of all injuries of the elbow-joint, and they are very well illustrated in the treatment of a *supracondylar fracture*. This results from falls on the outstretched hand or from direct violence. The line of fracture runs through the metaphysis close to the epiphyseal cartilage and the epiphysis may be displaced backwards and upwards, the degree of such displacement varying according to the severity of the accident. The child presents itself with a painful swollen elbow, the swelling having come up very rapidly. In order to obtain a good functional result early reduction of this fracture is essential. Under an anæsthetic the arm must be pulled out into full extension and whilst traction is being thus applied the forearm should be flexed up. After reduction has been accomplished it is not necessary to fix the joint in full flexion at once. Fix the forearm with a collar and cuff in that degree of flexion which can be obtained without any interference of the circulation resulting. The swelling around the elbow-joint rapidly subsides and the degree of flexion may then be increased. Keep the arm in full flexion for a week, and then gradually lower to a right angle, permitting the patient active movements through the free range. When the arm has been lowered to a right angle the collar and cuff may be removed and the patient allowed the arm free.

Under no circumstances should deep massage or passive movements be given in injuries of the elbow-joint. They cause pain and excite muscle spasm, hence diminishing the range of movement which is already present, and in the particular injury we are considering they produce myositis ossificans. Full range of movement is obtained with active use, though it may take several months before full extension returns. Never try to hasten the return of movement in an elbow-joint by manipulation; it will always result in loss of movement instead of an improvement. In a certain number of injuries of this nature the reduction of the displaced epiphysis is difficult. Always hesitate before advising an open operation to replace it, for, in my experience, an open reduction results in a great amount of permanent stiffness. And what may not look perfectly satisfactory as a skiagram may yet result in excellent function.

The nightmare in the treatment of this injury is the onset of a Volkmann's ischæmic paralysis. It may be caused by interference with the circulation from too rigid flexion; therefore, diminish this if there is any doubt. It may result from a large extravasation of blood at the site of fracture, and if there is any question this must be evacuated. In some few instances it undoubtedly follows injury to the muscle at the time of the accident and is then inevitable.

Fracture of the internal epicondyle is caused by an abduction strain falling on the elbow-joint. The epicondyle is torn off and displaced downwards or, if the elbow-joint is opened up very much may become locked between the ulna and humerus. The treatment of this injury is an open reduction with fixation of the piece of bone torn off in its proper position either with catgut sutures through the aponeurosis, or by means of a bone peg. The elbow is then fixed in plaster for a fortnight at a right angle. Subsequently, when the plaster is removed, the patient is allowed and encouraged to use the arm, and no massage of any kind is allowed. If the epicondyle is not fixed back in position, it remains pulled down by the muscles arising from it, and the function of the elbow-joint suffers accordingly. As a late result the ulnar nerve may be stretched and paresis may follow. The displacement of the epicondyle is always much greater than the radiogram would suggest.

Fractures of the head of the radius give rise to a great interference with function. Minor cracks are best treated with the elbow fixed in plaster for a fortnight; then there should be active use and no other treatment. When the anterior portion of the head is broken off, its removal at an early date is indicated, the remainder of the head being left untouched. If the head is comminuted all the loose fragments must be removed, and in both instances the patient is most comfortable with plaster fixation for 14 days. Complete excision of the head of the radius is to be avoided if possible, for it is sometimes followed by the subluxation of the distal end of the ulna and a weak wrist.

Fracture of the olecranon.—If there is little separation, fixation in plaster at a right angle is all that is necessary; thereafter the patient is allowed active use. When there is marked displacement of the upper fragment they must be wired together, and fixation in plaster subsequently adds to the patient's comfort. Fixation at 90° flexion is the position of choice. The fragments lie in position well and the patient is comfortable. Active use is allowed after the plaster is removed. The old position of full extension for the treatment of this injury should be given up, since it is uncomfortable and often confines the patient to bed.

Fractures of the lower end of the humerus in the adult are either T-shaped or comminuted. The conservative treatment of these injuries, in my opinion, gives the most satisfactory functional result, even if it is not possible to restore the fragments to their proper position. Open operation with fixation of the fragments by means of plates or screws may result in perfect anatomical reposition, but it also produces a very stiff joint with little if any movement. Under an anæsthetic the displacement of the fragments should be reduced as much as possible, and the arm should be fixed at a right angle in a sling with a posterior plaster splint. After the pain has started to subside, the patient can be allowed to have radiant heat and encouraged to move the joint so long as muscle spasm is not excited.

It will be observed that I have constantly laid stress on the value of active movements as an aid to the restoration of function after injury to the elbow-joint. Also that I have expressed a dislike for massage and passive movements. The elbow-joint after an accident responds to rough handling by becoming stiff, and once it has done so full range of movement is seldom restored.

edicine have appointed their commissions of quiry which have found a counterpart in the ofessional medical associations. The reports of ese official and semi-official bodies, and the essays n the same subject by individual leaders of the edical profession, such as Prof. G. Roussy, have ielded an imposing mass of evidence. The conscien- ous investigator, who took the trouble to wade rough it all, would probably emerge from the ordeal ith the reassuring conclusion that, in regard to ertain cardinal points, most of the would-be reformers re remarkably unanimous, at any rate in principle. n some quarters there seems to have been a tendency o grow impatient with the state of chaos into which nedical education has slid, and to find a remedy in a lean sweep and completely new start. But it is pretty afe to prophesy that reforms will come by evolution rather than by revolution, and that the old edifice will be respected as far as its main architectural features are concerned.

Some reforms are already materialising. In January of this year the *Conseil supérieur*, after consulting the faculties and schools of medicine and the *Comité consultatif de l'enseignement supérieur*, adopted the practice of anonymous, written examinations, with an eliminatory function—a somewhat sinister expression—at the end of the first two years of study. This practice will come into effect at the beginning of the scholastic year 1933. It should comb out the undesirables early in their misguided careers if the faculties and schools of medicine are prepared to use this new weapon with severe impartiality. To promote such impartiality some would-be reformers have advocated another step—the appointment of travelling boards of examiners whose ignorance of personalities would be an automatic check on favouritism. Another suggestion, prompted by the same line of reasoning, is that students should be examined by other faculties than those to which they officially belong, so as not to benefit from nepotic adjustments. The objection raised to both these proposed remedies is that they would be too expensive.

Unanimity, in principle, has to all intents and purposes been achieved with regard to the adoption of a uniform system of medical education, and the addition of an obligatory sixth year to the curriculum. This sixth year is going to be a big bone of contention, and the subject of a new study by the faculties and schools of medicine. Many would like to see it allotted mainly, or even exclusively, to essentially practical work. It should be of special value to those students who are not successful in securing house appointments, and who in the past have not been able to enjoy enough clinical experience by partial or whole-time residence in hospital. Realisation of this in itself laudable principle must, however, largely depend on hospital accommodation. The beginning of the sixth year is, in the opinion of some authorities, a suitable point from which the future specialists and general practitioners should diverge, the one from the other. The future specialist would in this case spend both a sixth and a seventh year in the subject of his choice, whereas the future general practitioner would spend his sixth year in practical work as a hospital resident. Another function for the sixth year would be to serve as a reservoir for obligatory medical and surgical studies flowing over from the congested fourth and fifth years.

The teaching of preliminary studies such as physics and chemistry has inevitably come in for criticism. The modifications recommended in this field are in favour of such studies being given a more medical slant than heretofore. There is, in fact, a general demand for less theory and more practice; but at the same time, as indicated at the opening of this paper, there is a feeling, amounting to a conviction in some quarters, that it is a fundamentally unsound principle to let the student in his first year plunge into a world of morbid changes before he has familiarised himself with the normal by a systematic study of anatomy and physiology. These subjects can be treated on practical or theoretical lines; and many hope that the teachers will abate their scientific austerity in a way that will enable the future general practitioner to apply in his daily routine the lessons he has learnt from his study of physiology and anatomy.

Concrete reforms have been advocated in the *Presse médicale* by Dr. Leriche, who would have the student devote two years to the normal body, two to the morbid body, and the last two to hospital work. During the first two years he would learn in hospital how to examine the pulse and take the blood pressure, the percussion and auscultation of the normal heart and lungs, and the various other methods of exploring the body in health. He would thus master the radioscopic appearance of the bones and viscera in health, and learn from rectoscopy and the various other 'scopies what the rectum, larynx, nose, &c., look like in a normal person. During the two middle years of his curriculum he would study microbiology, parasitology, and the natural history of various morbid states. In his last two years he would walk the hospitals day and night, and study such subjects as pharmacology, therapeutics, obstetrics, hygiene, and preventive medicine. As for specialising, a minimum of two years should be required and, in the case of surgery, four years. The same writer would like to see the old diploma of *Maître juré en chirurgie* resuscitated. The formal recognition of such a diploma should be a check on the non-specialised doctor who, fancying he has a flair for operative surgery, undertakes it with a light-hearted and vicarious courage which some of his patients may learn to regret.

MEDICINE AND THE LAW

Medical Certificates and Non-attendance at School

AT a meeting of a regional education committee in Northern Ireland during September, surprise was expressed at the discovery that parents are not obliged to furnish school attendance committees with a doctor's certificate when children are unable to attend school. The Ministry of Education for Northern Ireland had written a letter to the local authority in Antrim stating that it was advised that education committees had no power to require a dispensary doctor to issue a medical certificate free of charge. There certainly appears to be no statutory basis for any such suggestion. The law in Northern Ireland (under Part VI. of the Education Act passed by the Belfast Parliament in 1923) resembles the English law to be found in Part IV. of our Act of 1921. The parent has a statutory duty to send the child to school unless there is "reasonable excuse"; it will be a good excuse if "the child has been prevented from attending school by sickness or any unavoidable cause." If the parent neglects his duty, the education authority can summon him to produce "information and explanation." Nothing is said as to the form this information or explanation should take, or as to

NOMENCLATURE OF MENTAL DISEASE

A PROJECT FOR ITS INTERNATIONAL UNIFICATION

BY DORIS M. ODLUM, M.R.C.S. ENG., D.P.M.
JOINT HONORARY SECRETARY TO THE NATIONAL COUNCIL FOR MENTAL HYGIENE

AT a scientific session of the European Committee for Mental Hygiene held in Paris on May 31st last, Dr. Henri Bersot (Landeron, Neuchâtel) presented a report dealing with the unification of international statistics in relation to mental diseases. At the World Congress on Mental Hygiene held in Washington in 1930 a standing committee on statistics was set up, the need for a common basis of nomenclature in mental diseases being recognised as fundamental. A glance at p. 13 of the sixth edition (1931) of "The Nomenclature of Diseases," drawn up by a joint committee appointed by the Royal College of Physicians of London, will be sufficient to show the unsatisfactory state of our present terminology, especially in regard to borderland conditions, which are classified under the generic term of psychoneuroses.

Dr. Bersot in his paper states definitely that he does not wish his draft scheme to be accepted absolutely, but merely to provide a broad general basis on which a common meeting ground may be established. In very few countries is there any attempt at a really scientific classification. The official statistics are mostly based on a classification which is drawn up rather with an eye to administrative than scientific considerations. It might be unreasonable to expect any radical change in official classification which would involve expense and loss of continuity, but sufficient modification could be made to enable each country to come into line with a common schema for the purpose of international statistics.

The classification tentatively put forward by Dr. Bersot relates only to established psychoses and defective mental development and is as follows :—

(A) Congenital troubles.
  (1) Oligophrenia.
    (*a*) Idiocy.
    (*b*) Imbecility.
    (*c*) Feeble-mindedness (*débilité*).
    (*d*) Cretinism.
(B) Endogenous psychoses.
  (1) Affective psychoses.
    (*a*) Mania.
    (*b*) Melancholia.
    (*c*) Other forms.
  (2) Schizophrenia.
  (3) Other forms.
(C) Reactive psychoses (*psychoses réactionelles*) (probably better described as adventitious or exogenous).
  (1) Psychogenic type, hysteric (*par psychogénie, hystéric*).
  (2) Other forms.
(D) Symptomatic psychoses.
  (1) Resulting from uræmia, diabetes, &c.
  (2) ,, ,, nervous diseases, &c.
  (3) Other forms.
(E) Organic states—encephalopathies.
  (1) General paralysis.
  (2) Cerebral syphilis.
  (3) Pellagra.
  (4) Encephalitis, various forms.
  (5) Senile psychosis.
  (6) Post-apopletic psychosis.
  (7) Post-traumatic psychosis.
  (8) Cerebral tumours.
  (9) Other forms.
(F) Epilepsy.
  (1) Essential or idiopathic.
  (2) Other forms.
(G) Toxic psychoses.
  (1) Alcoholism, various forms.
  (2) Morphinism.
    (*a*) Simple.
    (*b*) With complications.
  (3) Cocainism.
  (4) Other forms.

Dr. Bersot points out that the subtitles are not intended to be cut and dried, but merely to serve as illustrations. The essential is to agree upon the categories. Obviously the classification is incomplete, but the principle is important and is not wholly incompatible with the classification of the R.C.P. Nomenclature, the main headings of which are:

(1) Mental deficiency (amentia).
(2) Psychoses accompanying organic diseases.
  (*a*) Endogenous.
  (*b*) Exogenous (i.e., those resulting from the ingestion of poisonous substances).
  (*c*) Psychoses with primary degenerative brain changes.
  (*d*) Infective exhaustion psychoses.
(3) Functional psychoses (which include the affective and reactive groups of Bersot).
(4) Epileptic psychoses.

Dr. Bersot's scheme does not make any attempt to deal with borderland or psychoneurotic types, and it is precisely in regard to these that the R.C.P. Nomenclature is least satisfactory. The so-called psychoneuroses, with all their subheadings of neurasthenia, psychasthenia, and the like, are badly named, since the predominant factor is neither one which concerns the psyche or intellectual faculties nor the neural system as such, but is essentially a disturbance of the effective life which has secondary effects on the neurochemical functions of the organism. As it is the affective element which is predominantly concerned, the generic term "dysthymia" would appear to be acceptable. Those psychoses which the Bersot scheme called *psychoses affectives* would then come under the group "psychothymia" which is practically synonymous, and the cyclothymic syndrome (manic depressive)—which in some people is so extreme as to constitute a psychosis and in others so mild as to be no more than an instability of emotional equilibrium—would naturally find itself placed under the psychothymias or dysthymias, according to its severity. The R.C.P. Nomenclature has also a heading "Psychopathic personality," which in the present state of our knowledge is probably the best term available, although it is not quite in line with the continental word "psychopaths" which has a much wider connotation.

International statistics will probably be among the subjects to be discussed at the next reunion of the European Committee for Mental Hygiene, to be held in Rome in September, 1933, when it is hoped that individual psychiatrists and government officials will meet to discuss nomenclature and classification on a common international ground.

WHAT IS WRONG WITH THE MEDICAL CURRICULUM IN FRANCE?

(FROM OUR PARIS CORRESPONDENT)

IT would be easy and fairly accurate to answer this question with : Same as in Great Britain. There are however certain divergencies, of historically remote origin, in both the theoretical and practical education of the medical student in the two countries. One such divergency may be mentioned at once. In France there is an old tradition which sends the medical student straight to hospital in his first year. Discontent with many aspects of the French medical curricula led, some time ago, to their scrutiny by various bodies, from the *Conseil supérieur de l'instruction publique* downwards. Faculties and schools of ditions and supervision in such cases might be that was necessary. Education was a vital cessity in the treatment of tuberculosis. It was ential to fill the minds of patients with positive erests.—Dr. STEPHEN J. MAHER (New Haven, nnecticut) said it was a mistake to suppose that e ordinary arrested or cured case of pulmonary berculosis needs to be coddled and trained for ng periods in some intermediate institution before ing allowed to resume his old ideas about the portance of time, money, and achievement. Failure secure employment was largely due to wrong ideas out the contagiousness of tubercle among adults. he profession must now fight these ideas, and at the resent time of economy it must concentrate on ring patients in the sanatorium instead of asking or "post-graduate" schools, factories, or villages.

The social events of the conference were memorable. xcursions were arranged throughout Holland, to laces of medical interest and elsewhere, with the nobtrusive efficiency characteristic of the country.

THE OXFORD UNIVERSITY PROVIDENT ASSOCIATION

AN association has been formed in order to meet the special medical needs and risks of Oxford undergraduates. It is designed to give the student (1) early medical advice and adequate nursing accommodation in the event of illness or accident, and (2) a substantial contribution towards the expenses of operation and nursing when these are unavoidable. The contract is a personal one, renewable from year to year at the discretion of the member and of the Association, and, once the initial waiting period of three months has elapsed, the benefits apply to sickness or accident anywhere and at any time in the year. The annual premium is £3, and the benefits obtainable are as follows :—

(a) *Nursing.*—A contribution not exceeding £6 per week for a period up to four weeks towards the cost of maintenance in a nursing home or in a private paying bed of a hospital (maximum £24 in any year).

(b) *Investigations and consultations.*—A contribution towards the fee of a consultant of £2 2*s.* or £3 3*s.*, according to whether the patient visits or is visited by the consultant (maximum £8 8*s.* in any year), and a grant not exceeding £3 3*s.* for X ray examination and not exceeding £2 2*s.* for pathological examinations.

(c) *Surgical operations.*—Contributions not exceeding £21 in any year towards surgeon's fees.

(d) *Anæsthetics.*—Contributions not exceeding £2 2*s.* in any year.

(e) *Electrical and massage treatment.*—A grant at rates not exceeding 10*s.* 6*d.* per treatment (maximum £3 3*s.* in any year).

(f) *General medical services.*—Contributions of two-thirds of the fees of general practitioners (maximum £8 in any year).

The liability of the Association is limited (*a*) to the payment of £63 to a member in any one year, and (*b*) to the payment of £63 to a member in respect of any one operation or illness. The arrangements for professional services and treatment are entirely in the hands of the member, in consultation with his doctor.

The Association is for mutual benefit only. The council includes among its members the Master of Balliol, the Warden of Wadham, the President of Magdalen College, Oxford, and the Principal of the Society of Oxford Home Students, with Sir Farquhar Buzzard as chairman. Although the Association was only registered during the vacation, and term has not yet started, nearly 700 applications for membership have already been received. Further particulars can be obtained from the registrar at 116, St. Aldate's, Oxford.

THE SERVICES

COMMISSIONS IN THE ROYAL ARMY MEDICAL CORPS

Twenty-five permanent commissions in the Royal Army Medical Corps are being offered to qualified medical practitioners, under 28 years of age. There will be no entrance examination, but candidates will be required to present themselves in London for interview and physical examination on Oct. 21st. Applications should reach the War Office not later than Oct. 14th. Further information may be obtained, either by letter or in person, from the Assistant Director-General, Army Medical Services, the War Office, Whitehall, London, S.W. 1.

ROYAL NAVAL MEDICAL SERVICE

Surg. Lt. M. J. Brosnan is transferred to the Permanent List.

The following appointments are notified: Surg. Lt.-Comdrs. M. Barton to *Pembroke*, for Chatham Dockyard; T. G. B. Crawford to *Pembroke*, for Chatham Hospital; and T. L. J. Barry to *President*, for course. Surg. Lt. T. W. Froggatt to *Vivid*, for R.M. Infirmary, Plymouth.

ROYAL NAVAL VOLUNTEER RESERVE

Surg. Comdr. A. G. V. Elder is placed on the retd. list.

Proby. Surg. Lt. A. P. Gorham to be Surg. Lt.

ROYAL ARMY MEDICAL CORPS

Lt.-Col. T. B. Moriarty, having attained the age for compulsory retirement, is placed on ret. pay.

Maj. R. M. Dickson to be Lt.-Col.

Maj. W. H. Cornelius is placed on the half-pay list on account of ill-health.

The undermentioned from the secd. list are restd. to the estabt.: Majs. J. W. C. Stubbs and J. R. N. Warburton.

Lt. R. H. Small relinquishes his temp. commn.

Lt. J. M. Ryan to be Capt. (prov.).

ARMY DENTAL CORPS

Lt. E. C. Browne to be Capt.

INDIAN MEDICAL SERVICE

Lt. D. H. Waldron to be Capt.

Lts. (T.C.) C. H. Dhala and S. D. Dalal to be Capts. (T.C.).

ROYAL AIR FORCE

Flying Officer G. A. M. Knight is promoted to the rank of Flight Lt.

CONFERENCE ON CONTRIBUTORY SCHEMES.—The second annual conference of the British Hospitals Contributory Schemes Association was held at Torquay last week under the presidency of Major B. J. T. Ford, chairman of the Birmingham Association. Mr. T. W. Place, secretary of the Birmingham Association, read a paper on the Value of association in advancing Contributory Scheme Principles. He said that experience had shown that the rate of contribution required in order to finance a scheme to provide reasonable support for institutions giving treatment to its contributors was approximately 3*d.* per week per member. This was the maximum sum which the average worker could afford to pay, and the average contribution of most "flat rate" and "1*d.* in the £" schemes. A contributor transferring from one district to another should be considered eligible to participate in the privileges of the new scheme immediately. This gave the contributor a sense of security, and would do much to popularise the system. On the question of payments to municipal authorities Mr. Place read the recommendation of the executive committee that a contributory scheme should not make payment at higher rates than the authority would obtain by the normal process of direct assessment of patients or those liable to be charged on their behalf. He believed that an average of £1 per case was a reasonable sum to pay.

the evidence in support thereof. If what the parent says is unsatisfactory, a school attendance order can be made and a court of summary jurisdiction can enforce the order. In Northern Ireland, as in England and Scotland, there is a wide statutory power for the department to frame "grant regulations" governing the payment of local authorities' expenses in connexion with education. There is also, as in England, a statutory duty imposed upon the education authority to arrange for looking after the health and physical condition of school-children and to provide for medical inspection. None of these enactments, however, quite covers the case of paying for medical certificates where illness causes inability to attend school, or of exacting such certificates, without payment, from a dispensary doctor.

INTERNATIONAL UNION AGAINST TUBERCULOSIS

(FROM A CORRESPONDENT)

THE International Union against Tuberculosis, now in its fifteenth year, held its eighth international conference in Holland from Sept. 6th–9th. It is usual to select three topics for debate, concerned with biological, clinical, and sociological aspects of the disease. This year were chosen questions which are probably as controversial as any which authorities on tuberculosis have to consider—namely, (1) The Relations between Allergy and Immunity; (2) Treatment with Gold Solutions; and (3) Post-sanatorial Care of the Tuberculous.

Speaking on the first subject Prof. **JULES BORDET** (Brussels) distinguished between congenital and acquired immunity. Allergy, he said, was also an acquired property and probably favoured bactericidal action of the blood, but alone it was not sufficient.—Prof. **LYLE CUMMINS** (Cardiff) defined the problem more closely in a paper dealing with the relation between hypersensibility to the products of the tubercle bacillus and the augmented defensive powers against disease which result from infection. The increased "anti-resorptive" or anti-disseminative power possessed by allergic animals was clearly proved, he said, but according to A. R. Rich it was not due to allergy but to some other factor. Prof. Cummins, in South Africa, had not found that highly allergic individuals were resistant to tuberculosis. The facts were, indeed, the other way, the more marked the allergy the greater the activity of the disease. He believed that all the known manifestations of allergy—local, general, and focal—as produced by tuberculin tests, were harmful. Modern therapy tried to avoid allergic phenomena in the patient in order to shield the immunity factors. They were antagonistic to one another, although called into being by the same stimulus.—Prof. A. **CALMETTE** (Paris) said that allergy merely revealed the state of infection. It could not be considered part of immunity, for organisms which were refractory to tuberculous infection never became allergic if one injected into them the bacilli which were virulent to sensitive subjects. These factors which had an inhibiting effect on allergy had no influence on immunity. The principle of treatment by tuberculin was to make allergic phenomena disappear, but this did not lessen the resistance to reinfection.—Another aspect of the subject was considered by Dr. **WILLIAM C. WHITE** (Washington) who distinguished between the various chemical fractions which composed tuberculin.

In opening a discussion on the Use of Gold Therapy Prof. **LUIS SAYÉ** (Barcelona) said it was agreed that the best time for the use of gold salts was the early stages of the disease before ulceration and fibrous tissue have become prominent. But he did not therefore discountenance their use in advanced cases, for definite improvement could be shown in radiograms and the favourable results were increasing year by year. In the early stages, the successful results were over 80 per cent., and even with advanced cases, 25 per cent. of patients were benefited. The treatment might have an important contributory effect upon the success of pneumothorax. Ambulatory patients and children were good subjects, and in his experience, absolute intolerance was not found in more than 3 to 10 per cent. of cases.—The same optimistic view as regards intolerance was taken by Dr. L. S. T. **BURRELL** (London) who grouped the unfavourable reactions under the heading of fever, usually subsiding if the treatment is discontinued; albuminuria, of which he had never seen a severe case with moderate dosage; and skin reactions, probably the result of the accumulation of the gold in the body. In his experience of the remedy, the amount of sputum diminished under treatment, tubercle bacilli lessened or disappeared, and fibrous tissue increased. He had had best results from Sanocrysin and Crisalbine.—Dr. **BURNS AMBERSON** (New York) had reached an opposite conclusion. In comparing two groups of cases (admittedly small in number) he had not found beneficial effects, although the patients had been controlled carefully. Any remedy, Dr. Amberson pointed out, might be successful in early cases.—Prof. G. **SCHRÖDER** (Schömberg) thought it certain that the action of sanocrysin did not depend on actual killing of the bacilli. He believed that the drug stimulated the reticulo-endothelial system. Solganol oil was a useful adjuvant to gold treatment.

On the third question, the After-care of the Tuberculous, the opener, Dr. B. H. **VOS** (Hellendoorn Sanatorium, Holland) spoke purely as a clinician, and throughout his paper emphasised the importance of clinical control and supervision for each case. In Dutch sanatoriums, patients are kept until they are able to work for eight hours per day. Sheltered employment was the rule. Dr. Vos spoke of industrial settlements and considered that the financial aspect of the duration of the patient's stay in the colony was still unsettled. The need for after-care could be reduced by improvement in clinical treatment and by more intensive development of occupational therapy.—Dr. H. A. **PATTISON** described the work at Potts Memorial Hospital, New York. Many of the cases needing after-treatment acquired tuberculosis before they acquired the knowledge of any trade. They needed strictly vocational training. He described a variety of occupations for which his institution tried to cater. At Tomahawk Lake Camp, the average period of residence was ten months.—Dr. **HARLEY WILLIAMS** (London) described the arrangements for care work in Britain, chiefly by means of care committees, which were being organised in all parts of the country, partly voluntary and partly as an official subsidy. He deprecated the use of the term "after-care" on the ground that the patient has to be considered a member of a family unit.—Dr. **JANE WALKER** (London) would like to see simple houses of residence, established for those cases which are likely to last for some years with no great chance of improvement. Simple nifestations in these two cases was very striking. both the lesions were remarkably persistent and ractable to all the usual forms of treatment, which d been vigorously pushed from the commencement. e type in both might be called psoriasiform, with e reservation that the colour and depth of infiltran made it quite evident that the latter disease uld not be considered. The striking feature in the ale patient was the tendency to pigmentation, both the stains and cicatrices of the healed lesions and, pparently, quite apart from them around the posrior aspect of the neck. The tendency was not pparent in any of the other resistant cases in this ries. The W.R., as stated, was positive in the case the woman at the conclusion of her course, and at e time when the secondary eruption first appeared, hile in the man it was negative throughout. From is instance, then, it might be argued that the blood eaction plays little or no part either in the production r prevention of the arsenic-resistant eruptions. The V.R. reports in such cases have frequently exhibited pparent contradictions. The usual divergence is a ero-negative clinical relapse, with a return to the ositive phase when the eruption begins to involute. n the above cases it is interesting to note that the voman, whose manifestations yielded more readily han the man's, had a positive test, while his was egative during the period of their greatest activity. I have had no opportunity of determining the present state of the blood.)

Case 3.—Mr. C., aged 36, a hospital patient, provides another example of the resistant syphilide. On Jan. 20th, 1932, spirochætes were demonstrated in his small superficial coronal sore, and by the first week in March 4·5 g. of N.A.B. and 7 c.cm. of bismogenol had been injected. On April 20th the W.R. was positive, and a second course of 4·8 g. of N.A.B. was given. During this period a psoriasiform eruption developed on the extremities, on the back, and round the nipples. There was superficial scarring in some of the lesions, but no adenitis. This eruption was still active on July 22nd and the W.R. was positive. On August 2nd jaundice developed, so that N.A.B. injections could no longer be administered.

Case 4.—Mr. D., aged 33, developed a maculo-papular eruption while under treatment for a gonorrhœal periurethral abscess on Nov. 3rd, 1931. The, W. R. was strongly positive. The usual weekly injections of N.A.B. (4·5 g. in all) and intramuscular bismuth completed the first course on Jan. 5th, 1932. On the 12th anal condylomata appeared, and on the same day 0·25 g. of silver salvarsan was administered and repeated weekly with iodides by the mouth until March 23rd. On Feb. 8th the voice became husky, and psoriasiform lesions were noted on the arms. On March 15th there was dysphagia, and the laryngologist reported a syphilitic glossitis, with swelling of the epiglottis and ary-epiglottic folds. The patient was ordered large doses of Zittmann's decoction (Decoct. Sarsæ Co.). The W.R. was strongly positive. As skin lesions were still active on March 30th a fresh course of silver salvarsan (1·15 g.) was given, but on April 26th it was noted that "typical condylomata on the scrotum and papular scalp lesions had made their appearance." On May 4th treatment with Bivatol (a soluble preparation of bisalicylate in oil) was begun and given intramuscularly twice weekly until June 17th, 16 c.cm. in all. Improvement followed the first two injections, and healing of all symptoms was complete on the latter date. On July 15th, three and a half months after the last arsenic injection, the patient developed jaundice, which fortunately proved to be transient, so that the bismuth injections were shortly resumed.

Case 4, which clearly belongs to the arsenic-resistant group, illustrates the contention put forward by Nicholas, Lebeuf, and Charpy,[2] that bismuth will often succeed where various members of the arsenobenzine series have failed to effect a clearance of the cutaneous lesions. Case 5 is the only one of my series that supports Colonel Burke's view that arsenic-resistant syphilis is the result of inefficient treatment at the outset.

Case 5.—Mr. E., aged 24, presented himself with a primary chancre on August 5th, 1930, but neglected to attend after his second injection of N.A.B. A month later he reappeared with impetiginous lesions on the body, and unmistakable syphilitic palmar lesions of a psoriasiform type. His attendance continued to be irregular, but injections were given on Oct. 14th and 21st. On the 22nd I noted a generalised eruption of papular psoriasiform type. The W.R. was strongly positive. and a biopsy of one of the papules confirmed the syphilitic nature of the symptoms. This case also eventually yielded to intensive treatment with bismuth, the eruption having proved intractable after 3·9 g. of N.A.B. subsequently administered.

The criticism of inadequate treatment cannot apply to Case 6—the last of my series.

Case 6.—Mr. F. presented himself on March 7th 1932, with a penile sore of a week's duration. Spirochætes were found in plenty, the W.R. was negative, and between March 7th and May 18th he received 5·15 g. N.A.B. and 11 c.cm. of bismogenol. A month later he began his second course, and had been given 2·25 g. when on August 3rd he developed diarrhœa and vomiting, so that no injection was given on the 10th. The following week an infiltrated crusted lesion appeared in the site of the original penile chancre, and 0·2 g. of silver salvarsan was injected. This had no effect on the lesion which was seen to be spreading the following week. As in the other cases, a satisfactory clearance was achieved with bismuth.

Whatever the mechanism of production of the arsenic-resistant case, and supposing for a moment that inadequate treatment is the cause, there still remains the problem that such cases appear to be increasing, as anticipated by McIntosh and Fildes in 1911.[4] Drake and Thomson illustrate the increase graphically, and while their schedule of treatment (even if it is inadequate according to modern standards) has not varied since 1927, there has been a progressive increase of clinical and serological relapses since that date to the present time. In my own cases, with the exception of Case 5, the treatment had been orthodox and the attendances regular, and yet these malignant resistant symptoms developed—in Case 4 *actually during a course of injections*, and ergo, in spite of it. It seems to me that a theory of inadequate attack entirely fails to explain a failure of this kind. It will be noted that the type of relapse in Drake and Thomson's series is the gumma. I have had no instances of this either in private or hospital practice. The cases detailed above are of the late secondary order, and seem to me to fall into a category which is not comparable either to the gummatous or the far more common serological resistance or relapse. I should be greatly interested to know if they are unique or whether any of your readers can amplify the abnormality of reaction from their own experience.

In conclusion, I should like to associate myself with the opinion expressed by Dr. Browdy, that it is not syphilis but syphilitics we are to treat. While it is necessary to have a working basis of treatment, we must treat individuals as necessity demands.

I am, Sir, yours faithfully,

HENRY C. SEMON, M.D., M.R.C.P.

London, W., Sept. 23rd, 1932.

DEATH CERTIFICATION

To the Editor of THE LANCET

SIR,—I read with great interest and agreement the letter of Dr. Jameson on the subject of death certification, which appeared in your issue of August 20th (p. 419). I also noted that in your observations on Dr. Jameson's communication you intimated that it is the definite policy of the General Register Office to rely upon the opinion of the certificate and not upon arbitrary rules.

With great respect, may I venture to doubt if the desirable practice mentioned by you is really

CORRESPONDENCE

WANTED A HOSPITAL EXCHANGE IN LONDON

To the Editor of THE LANCET

SIR,—May not some system of centralisation for the admission of urgent and acute cases to the several general hospitals be adopted, somewhat on the lines of the County Council's fever hospitals services? Many general practitioners have probably at some time or other experienced the greatest difficulty and delay in finding hospital accommodation for an urgent case; telephone inquiries, interminable waiting, more inquiries, and then more waiting, and in the end, perhaps, nothing—a negative result, no vacancy! I can recall occasions when I have spent over an hour endeavouring to find hospital accommodation for an acute abdominal case.

Such a state of things is harassing to doctor and patient alike, and I would suggest the establishment of a central body, or bureau, which would deal with all the available local hospital accommodation, and allocate cases for admission when the need arose. Although there are undoubted difficulties in connexion with the administration of such a scheme—which differs in some respects from the example quoted above—yet I feel sure that these are not unsurmountable, and that the value of such a service can hardly be gainsaid.

I am, Sir, yours faithfully,
LOUIS M. LEVENTON, L.R.C.P. & S.

Liverpool-road, N., Sept. 23rd, 1932.

THE INCREASE IN ARSENIC-RESISTANT SYPHILIS

To the Editor of THE LANCET

SIR,—The issue raised by Dr. Sequeira is well timed and deserving of careful consideration by all interested in the modern treatment of syphilis. His purpose will not be well served by Colonel Burke's assertion that dermatologists fail to recognise that syphilis is not a cutaneous disease, but a general infection of the cardiovascular system. I hope to offer some evidence that there are grounds for the thesis put forward by Drake and Thomson in the paper referred to by Dr. Sequeira, and that, whatever the cause, inefficient or inadequate treatment is not the main or even a frequent factor. With the question what should constitute adequate treatment I do not propose to deal at present, although I submit that in five out of my six cases here cited the treatment was entirely adequate in the accepted sense of the term, and yet failed to prevent the onset of symptoms which can only be characterised as arsenic-resistant.

Before quoting my own cases I would refer briefly to the remarkable case instanced by Kloeppel.[1]

This was a man who contracted an atypical chancre three and a half weeks after coitus, and infected his wife three weeks later. There were copious spirochætes in the discharges of both primary lesions, and the Wassermann test was negative in both patients. The man was given no less than 2·3 g. of neosalvarsan in divided doses in eight days—the woman 1·05 g. in 7 days (a total that should appease the most strenuous of *venereo-therapists*)—without the slightest effect on the clinical appearances or on the apparent viability of the organisms. The lesions cleared up promptly on substituting a mercurial intravenous injection for the arsenical, and the author argues with seeming justification that the strain of the infecting organism must therefore have been arsenic-resistant.

It is not often that the partners in a luetic infection are simultaneously under treatment by the same physician, and as cases of resistant syphilis are relatively rare, I count myself fortunate in being able to report a dual infection of a resistant character.

CASE 1.—Miss A., aged 29, consulted me on April 13th 1932, for a crusted and slightly irritable eruption on the scalp, both palms, and right anguli oris. These symptoms had been present since January, when there were also some vulvar sores, following a risk taken in October, 1931. The W.R. was positive, and this in spite of a course of eight injections of sulpharsenol (3·3 g.), which had concluded in the last week of March. There were no buccal or pharyngeal lesions and no adenitis. In view of the failure of N.A.B. to prevent this clinical and serological relapse, and of the supposed more potent action of the silver salt, 0·15 g. was injected on April 13th. Slight improvement of the mouth lesion followed, but the crusting of the scalp and the palmar patches were not influenced perceptibly. On the 20th 0·2 g. neo silver salvarsan was given, and was accompanied by flushing and nitritoid symptoms, not pronounced enough to require adrenaline. On the 28th the mouth lesion had cleared up, but the scalp and palms showed little change. On May 5th, in view of the previous nitritoid tendency, 0·45 N.A.B. was given in 10 c.cm. Afenile (10 per cent. calcium chloride and urea solution), but in spite of this precaution the patient felt unwell, and had abdominal pain and diarrhœa on the following day. Two further injections of 0·15 N.S.S. were given on May 13th and 20th, but both the scalp and palmar lesions were still present although improving on the 27th, when she was last seen and referred to her home practitioner for bismuth injections for a period of six weeks.

Palmar lesions seem to be particularly common in this resistant type of syphilis. They occurred, as will be seen, in the case of this patient's partner, and in two of our hospital cases, and is stated by Nicholas, Lebeuf, and Charpy,[2] to be a relatively common manifestation.

CASE 2.—Mr. B., aged 42, who admitted responsibility for the infection of the preceding case, contracted the disease in August, 1931. A chancre appeared [illegible] observed on Oct. 22nd. The W.R. was already [illegible] of N.A.B. (7·0 g. in all) and ten [illegible] were given in weekly doses for the remainder of October and in November and December. In the first week of January an eruption appeared on the trunk and extremities. Three more intravenous injections of N.A.B. had no effect, in fact they appeared to aggravate it. Six weekly injections of silver salvarsan and iodide by the mouth were advised, and when I saw him on July 21st, 1932, I made the following note: "It is a deeply infiltrated scaly, nummular, psoriasiform eruption. There is a marked tendency to pigmentation, not only of the residual cicatrices, but of otherwise normal skin, especially on the neck and shoulders. Of the active lesions, varying in size from a threepenny bit to half-a-crown, some are covered with crust, others scaly. On the scalp the condition is that of a moderate seborrhœa, and there are no ulcerative tendencies as in Miss A., although as in her case there are infiltrated circinate lesions on the palms. There is no adenitis, and the W.R. has been negative on three occasions since the eruption first appeared in January." In view of the compete failure of the arsenobenzole group to achieve a clearance of the eruption it was decided to try the effect of protein shock methods. Malaria having been refused, Aolan (detoxicated milk), 5 c.cm., were injected intramuscularly into each buttock on July 21st, 1932. A pronounced febrile reaction resulted on the following night, and on the 27th the eruption was decidedly less crusted and infiltrated and no fresh lesions had appeared. Two more 5 c.cm. injections of aolan and iodides by the mouth were advised, and three weeks later the eruption had been replaced by stains and soft cicatrices, and no fresh lesions were noted.

This favourable issue supports the advocacy of Beume[3] for the value of whole blood injections—an even milder protein shock effect—in cases of salvarsan-resistant syphilis. The patient has now been having two injections of bismogenol, 1 c.cm. each, per week, and except for his pigmentation is entirely free of symptoms. The general resemblance of the clinical al crisis. Temp. fell from 104° to 102° F. in six hours. the third day a refill brought down temp. in 12 hours to Discharged well on March 15th. 1932.

ASE 5.—Male. aged 38. admitted March 21st, 1932. for r. cough. and pain on the left side of the chest, duration days. Left basal consolidation with pleurisy. A.P.) c.cm.) on the first day. Temp. fell from 105° to 102° F. eight hours. with no marked diminution of respiratory e. Relief of pain immediate. Temp. oscillating °–103° F. for next two days. On third day a refill sed a drop in the temp. in three hours, rose again next rning to 102.° Another refill brought the temp. down to rmal in 10 hours time. After oscillating for another day two temp. remained normal from March 28th. Disarged on April 3rd. 1932. In this case definite crisis curred only after the third refill. Patient became irious the day after induction and remained so till the ond refill.

CASE 6.—Male, aged 21, admitted March 24th, 1932, for ver and pain on left side of the chest of five days' duration. mmencing consolidation with fibrinous pleurisy on the t base. A.P. on night of admission. Pain immediately lieved. Temp. fell from 105° to 102° in eight hours. Since did not fall below 102° for the next two days a refill was ven on the third day. Crisis occurred after 24 hours. his patient also became delirious the day after A.P. ischarged well on April 3rd, 1932.

CASE 7.—Male. came with a history of nine days' fever nd cough. Consolidation of whole of right lung. A.P. n second day after admission. Temp. fell from 103° F. to ormal in 20 hours. There was no subsequent rise.

I agree with Dr. Coghlan that the induction of A.P. gives immediate relief from pain. As regards emperature, in all my cases except one. the drop occurred only after six hours, whereas in his the crisis occurred within three hours. Only in two cases did the temperature drop to normal after the first nduction. In all other cases there was only a fall of two or three degrees. In two cases only did profuse perspiration occur after A.P. There is no doubt that A.P. does produce an artificial crisis, often temporary, sometimes permanent; in our cases, the crisis was more delayed and less dramatic than in the cases described by Dr. Coghlan. He claims that dyspnœa is relieved in half an hour. I was not so fortunate in my results. for though the respiratory distress was relieved owing to disappearance of pain, the rate of respiration came down only with the fall in temperature. Though my results were not so brilliant as Dr. Coghlan's I am of opinion that treatment with A.P. deserves a trial in pneumonia. In cases of acute pleurisy the results are really dramatic. In lobar pneumonia it is an important auxiliary to other forms of treatment. But, as Dr. Coghlan says, lobar pneumonia is emphatically not the disease on which to gain a knowledge of the technique.

My thanks are due to Colonel Skinner for allowing me to try this method of treatment on his cases. I am indebted to Dr. J. Mani for helping me in the operations.—I am. Sir. yours faithfully,

R. VISWANATHAN. M.D.,
Assistant Professor of Medicine and Assistant to First Physician, General Hospital, Madras.
London, Sept. 16th, 1932.

PATHOGENESIS OF CAVITIES IN THE LUNGS

To the Editor of THE LANCET

SIR,—I do not think Dr. Sowerbutts's paper carries us much farther with regard to the ætiology of the annular shadows. I agree with Dr. Andrew Morland when he says that it is far-fetched to imagine that air passes through the bronchial wall, giving rise to a single bleb or cyst. On the other hand, Dr. Morland's theory of the causation of vomicæ cannot possibly be accepted without careful research. It is partly based, if I do not misunderstand him, on the fact that Dr. Vere Pearson in an isolated case found a positive pressure in a large cavity. But any of us working at artificial pneumothorax therapy observe from time to time positive and negative pressures which cannot be explained from our knowledge of pulmonary physics. The "paradoxical reading" is an example. It is obvious that if you insert an artificial pneumothorax needle into a vomica you may. on the analogy of artificial pneumothorax. get either a negative. positive, or atmospheric reading.

During the last year my assistant, Dr. A. J. P. Alexander, has taken great trouble to get accurate information about every case with annular shadows admitted here, and he has reached the following conclusions, with which I entirely agree :—

(*a*) 5 per cent. of all patients admitted showed one or more rings.

(*b*) Tubercle bacilli were found in the sputum of all the patients who had these shadows.

(*c*) The rings altered in size in no definite direction or time.

(*d*) The study of these rings in a collapsed lung has been of no practical value.

(*e*) In most cases no definite physical signs were detected over them.

(*f*) All the cases showed extensive shadows.

The work, therefore, was leading us nowhere. The only point of any real value was that T.B. were present in every case. If a ring was evidence of tuberculosis this last observation might be useful.

When in Canada and America in 1930 I got the impression—erroneous perhaps—that they considered every ring as evidence of a cavity. Dr. Alexander. who has just returned from the German post-graduate course run by the Joint Tuberculosis Council, tells me he got this impression too. If this is correct, the ætiology of the rings is of great practical importance, because collapse therapy is likely to be adopted wherever they are found. As Dr. Sowerbutts says, the question can obviously only be settled in the post-mortem room. with a team consisting of the clinician, the radiologist, and the pathologist. To this team a physiologist might well be added. I am, Sir, yours faithfully,

J. D. MACFIE.
Winsley Sanatorium, near Bath, Sept. 24th, 1932.

LATERAL THORACIC JERK:
A SIGN OF ANEURYSM

To the Editor of THE LANCET

SIR.—When I wrote my account of the above sign of aneurysm of the descending aorta I mentioned having seen it with Dr. R. M. Scott, of Cleveland. in 1926. I have recently received a letter from Prof. F. C. Arrillaga, of Buenos Aires, calling my attention to a paper describing the same sign in the *Semana Médica* of April 9th. 1931, p. 937. Further papers by Dr. Arrillaga, with Dr. J. C. Dabove. appeared in the same journal later in the year (1931. ii., 7, 1253, and 1739), and he gives among others the following list of references to other authors which may be of interest to some of your readers :—

del Sel. M., and Taquini. A. C.: *Prensa Méd. Argent.*, 1931, xviii., 255.

Martini, T., and Joselevich, M.: *Semana Méd.*, 1931, ii., 1259.

Padilla, Cossio, and del Castillo: Ibid., 1932, ii., 76.

del Sel, Costa Bertani, and Gerlovich: *Prensa Méd. Argent.*, July 10th, 1932, p. 241.

Moia. B., and Dondo, H.: Soc. de Méd. Interna, August 26th. 1932.

I feel that without this letter the above references may elude readers in this country as they did me.

I am, Sir, yours faithfully,

GEOFFREY BOURNE.
Queen Anne-street, W., Sept. 26th, 1932.

adopted in the General Register Office. In my experience I have found that the application of the rule of selection is invariably followed, and any disease in a lower group is preferred to one in a higher, notwithstanding the opinion of the certifying practitioner. Recently a patient was admitted to a local hospital in a state of diabetic coma, almost moribund, and death occurred within a few hours. A post-mortem examination was made and evidence of pulmonary tuberculosis was found. The death was certified as follows: "(*a*) Diabetic coma, (*b*) Tuberculosis of lungs, (P.M.)." In a written communication the certifying medical officer informed me that, although tuberculosis had been found as a result of post-mortem examination, "the immediate cause of death was diabetic coma." A copy of this communication was, therefore, forwarded to the General Register Office, but notwithstanding this information I am officially informed that the cause of death is to be classified to tuberculosis. The recorded cause of death is, therefore, inaccurate, the written opinion of the certifying practitioner is ignored, and the strict rule of selection applied.

I am, Sir, yours faithfully,
G. SOWDEN.
Medical Officer of Health, St. Pancras.
Sept. 14th, 1932.

ANAPHYLAXIS FROM BEE STINGS

To the Editor of THE LANCET

SIR,—Dr. Goodman will find answers to most of his questions in a paper on Allergy in Relation to the Bee Sting, by R. L. Benson and H. Semenov.[1]

They consider the harmful effects of bees under three headings: (1) The venom of the sting, which *may produce a general and non-specific effect* of varying intensity depending upon the rapidity of absorption. The pharmacologically active principle of bee venom appears to be non-nitrogenous and has an action suggesting a saponin. This substance may act as a dermolysin releasing histamine actually present in the skin, but Benson and Semenov have conducted interesting experiments from which it seems probable that the venom itself may contain a histamine-like substance. This if introduced into a vein may produce shock. (2) Allergic reactions due to pollen carried by bees. Cutaneous allergic reactions can be produced experimentally by testing certain pollen-sensitive individuals with extracts from the bodies of bees, but clinically such a happening must be a very chance phenomenon. (3) Allergic reactions in the human from sensitisation to allergens inherent in the bee. These reactions are of increasing degree with successive bites and consequently common in bee-keepers. One of the earliest of these was that reported by A. T. Waterhouse.[2] Desensitisation in these hypersensitive individuals may be brought about by increasing doses of bee extract made from the posterior eighth of an inch of the bee's body. Dr. Goodman's case seems to fall into this category, but it is remarkable that the sting a week previously was without any ill-effects. Possibly this sting was only venom, and free from the intrinsic bee protein which seems responsible for this third group.

The poison gland system of the bee consists of a small alkaline and a larger coiled acid gland, the secretion of both of which is poured into the bulbous base of the poison canal and mixed to form the poison. From the canal it is expelled during the stinging act by a valve-like structure on each of the hollow darts forming part of the barbed shaft which is left behind in the victim's flesh with the sting.

In a recent publication[3] I have summarised the reported cases of allergic reaction to various insect stings, bites, and emanations.

I am, Sir, yours faithfully,
London, W., Sept. 25th, 1932. GEORGE BRAY, M.B.

TREATMENT OF PNEUMONIA BY ARTIFICIAL PNEUMOTHORAX

To the Editor of THE LANCET

SIR,—In your issue of Jan. 2nd (p. 13) Dr. J. J. Coghlan described 6 cases of pneumonia treated by artificial pneumothorax. I have up to now adopted this form of treatment in 11 cases at the General Hospital, Madras, 4 of them being cases of acute fibrinous pleurisy. In the first 3 cases I adopted Coghlan's method of giving morphia and atropine half an hour before the induction; in all the other cases morphia was not given, and I did not observe any difference. So as to cause the least possible disturbance the patient is allowed to lie flat on the back with the arm on the affected side raised over the shoulder. I choose an interspace in the anterior axillary line where the lung is not consolidated—a precaution which is unnecessary according to Coghlan. After sterilising the skin thoroughly, I infiltrate with novocain 1 per cent the whole track for the pneumothorax needle, including the parietal pleura. In my experience the inflamed parietal pleura is not so hypersensitive as Dr. Coghlan thinks; in two cases where I wanted to avoid two successive pricks, I performed the induction without novocain, the patients making no demur. In every case 500 c.cm. of air was *inserted at the* first induction, the amount being varied at the refills. In the cases of simple pleurisy no refill was given, nor in cases where crisis occurred and temperature remained normal after the first operation. I will add brief notes of the 7 cases of pneumonia.

CASE 1.—Well-nourished male, aged 35, admitted Feb. 15th, 1932, for fever and cough of four days' duration. Evident respiratory distress; temp., 101·5° F.; pulse, 120; resp., 40. Left basal consolidation. A.P. (500 c.cm.) on the second day of admission. The effect was dramatic. He had profuse perspiration in ten minutes and temperature came down to normal in two hours. This was the only case in my series in which a crisis occurred as early as in Dr. Coghlan's cases. Patient made an uneventful recovery.

CASE 2.—Male, aged 23, admitted March 7th, 1932, for fever, cough, and pain over the right side of the chest of 36 hours' duration. General condition bad though fairly well nourished. For two days signs indefinite, on third day definite consolidation of the right base with extensive pleural involvement. A.P. 500 c.cm. Pain immediately relieved. Temp. fell from 104° to 101·5° F. in six hours, with improvement in general condition. Developed delirium tremens the next day. Refill on sixth day after admission. Temp. fell from 104° to 99·5° F. in five hours, but rose again in a few hours and patient died the next evening. This case illustrates that A.P. induces an artificial crisis which does not *necessarily correspond* to the expected natural crisis.

CASE 3.—Male, aged 19, admitted March 7th, 1932, for pain on left side of chest and cough duration two days. Left basal consolidation, with well-marked pleuritic rub. A.P. 36 hours after admission. Temp. fell from 103° to 100° F. in five hours but rose again to 102° after two hours, and dropped to 99° the next morning—i.e., 18 hours after induction. As the evening temp. rose to 100° refill (500 c.cm.) given two days later. Discharged well on March 15th, 1932.

CASE 4.—Male, aged 30, admitted March 10th, 1932, for fever and pain on the right side of the chest and cough duration seven days. Consolidation of right lower lobe. A.P. on the same day. Pain immediately relieved, no

PANEL AND CONTRACT PRACTICE

Appeals to the Ministry of Health

If a complaint has been tried by a medical service bcommittee, and if either side is dissatisfied with e decision reached—and confirmed (or altered) by e main insurance committee—it may appeal to the inister of Health. The whole matter is then investi- ted again, but on this occasion legal help may be tained and all the evidence is given on oath before ficials of the Ministry—usually with a barrister in e chair.

In London it has lately been the custom, perhaps om motives of economy, for the clerk to the ommittee or his deputy to represent the insurance ommittee at these appeal cases. Previously counsel ere always briefed on these occasions, but experience eems to show that the clerk who has been present at he medical service subcommittee's hearing is quite apable of presenting the committee's case. At the ame time it is somewhat questionable whether it s good policy that the clerk of the committee, who hould really be an impartial administrator of the nsurance regulations, should be the person to marshal he evidence so as to ensure if possible that the views of the practitioner do not prevail.

In the nature of things most appeals are by doctors against a decision in which the medical service subcommittee has found in favour of an insured person. In these cases counsel (or latterly the clerk) appears to urge the committee's decision on the appeal tribunal. There is room for doubt, however, whether the committee's influence is used with equal force in favour of a doctor who is defending an appeal by an insured person against the committee's decision. Furthermore, in charges against a practitioner the latter is apt to be handicapped by the fact that the incident in question may only be remembered with difficulty as one of 30 or 40 in his day's work, whereas to the patient it is probably the only important event of the day. Even then the patient very often reports it wrongly, as can be proved later by prescriptions and written testimony.

There are, at present, some important outstanding cases whose appeals have not yet been heard. One of them, already described at some length in our columns, is the case of an elderly practitioner who was refused permission to employ an assistant on the ground that he, as principal, did not do enough personal work in the practice. The practice was being kept going for the widow until a son and daughter were able to qualify and carry it on.

PROBLEM OF A HOSPITAL STAFF

Another relates to the conditions of insurance practice at one of the hospitals in London, now under the control of the London County Council. This case was heard by the medical service subcommittee for London, and reported to the main committee last April. The decision was :—

> "That the committee are of opinion that there has been a complete failure on the part of the practitioner referred to in case M32/15 as Dr. A. to comply with the terms of service for Insurance Practitioners, either personally or by deputy, in respect of the insured persons for whose treatment he has accepted responsibility under the National Health Insurance Acts, and that the practitioner, the Approved Society, and the Minister of Health be so informed."

It should be noted here that no penalty—either caution, censure, or deduction from remuneration—is suggested. The case is interesting, and largely depends upon the right of an insured person to choose his own doctor. Shortly, the facts, as given in the report, are as follows :—

Most of the nursing staff of this hospital are insured persons, and as such have chosen the medical superintendent as their insurance practitioner. It has always been the custom for this hospital to attend to its staff gratuitously, and, if need be, to admit them to the wards. The duty of looking after all the staff (including the non-insured staff) has always been carried out by the senior assistant medical officer, who is now the surgeon specialist to the hospital, and as such is now no longer under the control of the medical superintendent. The complaint arose from an approved society. The society received a claim from one of its members on the hospital staff with a certificate, signed by the surgeon specialist, which was not on the proper medical form (Form Med. 40) but was as follows :—

> This is to certify that $\left\{\begin{matrix}\text{Nurse}\\ \text{Sister}\end{matrix}\right\}$ ....
> *is off duty owing to ill-health.*
> Taken off duty............
> Resumed duty............
> Signature............

The doctor was asked to supply a certificate on the proper form, but stated he was not an insurance practitioner, and he had a deep-rooted professional objection to stating on a certificate what was the matter with a patient, since that was a confidential piece of information. The society made the following points :—

1. The record card of the member could not, from the certificate in question, record the nature of the incapacity.
2. There was no indication whether the case was one for compensation.
3. Owing to the length of illness and absence of diagnosis the society could not tell whether the case should be sent for examination by a referee.

The society also stated that a certificate had been given three weeks in advance in connexion with the period of recuperation.

The report goes on to say that from the evidence submitted it appears that at the passing of the Act there was a discussion between Dr. A. (the superintendent) and Dr. B. (the senior assistant, now surgeon specialist) with regard to one of them accepting service under the Act in connexion with the treatment of the insured staff of the hospital. Apparently, neither was willing to accept service under the Act, but it was realised that if they did not do so the capitation fees payable in respect of medical treatment of the insured staff would be lost to the institution. It was eventually agreed that Dr. A., the superintendent, should enter into an agreement with the insurance committee that the money received by him under that agreement should be allocated to a fund for the benefit of the staff of the hospital, and that Dr. B. should continue to give the medical attendance as before—of course *gratuitously*. This arrangement has continued until the present time.

The question arose as to whether nurses or other members of the staff were entitled to medical treatment from the staff as of right. It was agreed that they receive it at this hospital as elsewhere—as of long-standing custom—and that it is the practice in such institutions for treatment to be provided by a particular member of the staff. The committee concluded from this statement that Dr. A., as administrative head of the hospital, is ultimately responsible for seeing that members of the staff receive any medical care and attention they require, and that the particular officer giving that care is really acting as

PUBLIC HEALTH SERVICES

Public Assistance Institutions in the Counties

MOST of the county poor-law institutions transferred under the Local Government Act, 1930, are of the mixed workhouse type, and very few have separate hospitals which can be taken over by the health committees. Although large expenditure on new buildings is prohibited by financial stringency, some of the reports show that many improvements are possible under existing conditions.

In ESSEX (est. pop. 1,195,100) Dr. W. A. Bullough says that the public assistance institutions need a careful survey, with the object of reclassifying the patients and the accommodation available, but that such a survey is impossible with the present staff. In the meantime many inexpensive extensions and alterations have been made.

Thus a day room for 50 casuals has been provided for the Colchester institution, which will be eventually closed when extensions to the modernised Stanway institution have been completed. Electric lighting has been installed at Tendring, and improvements to the children's nursery have been carried out at Braintree. Saffron Walden institution will be closed when it is possible to erect a new building at Takeley. Improvements have been carried out to the laundry at Epping, and the erection of a new nurses' home at a cost of £11,000 has been approved. A new nurses' home has been nearly completed at Orsett. Many improvements have been effected at the Oldchurch-road Institution, Romford, so as to secure an efficient maternity block. A special puerperal fever unit has been established at this hospital, which actually functions as a general hospital for a population of about 350,000. A special puerperal fever unit has also been established at Chelmsford; whilst at Maldon there are 100 unused beds, the future of which is under consideration. A consulting staff has been appointed for the benefit of the 4 to 5 thousand inmates in these institutions, and will chiefly operate in connexion with Oldchurch Hospital.

Many administrative changes have been introduced. The amount of alcoholic liquor is to be reduced and its use standardised. Arrangements have been made for the improvement of the milk-supply. Steps have been taken to reduce the prevalence of bedsores. Waking hours have been under consideration. The average time for awakening the patients was 5 A.M., whilst the average time for the first meal was 7 A.M. The question of dietaries has received much attention and an attempt is being made to provide each inmate with a helping in accordance with appetite instead of the prescribed quantity laid down. Apparently the actual quantity of food mentioned in the orders of 1913 and 1930 has to be available, even if not actually served on the tables. The grading and salaries of the nursing staffs are under consideration, and it is intended at an early date to establish a county nursing service, whereby suitable candidates from the secondary and other schools can secure their three years' training in the county institutions.

In NORTHANTS (est. pop. 218,300) the report of Dr. J. M. Mackintosh shows that improvements have been made in the provision for the aged and infirm and the chronic sick. These have been secured by extensions at Kettering, whilst another extension at Oundle will enable the existing institution at Thrapston to be closed. The more difficult problem of providing modern accommodation for the sick and aged in the west of the county is to be met by extensions of the Daventry institution, which will enable the out-of-date mixed workhouses at Brackley, Brixworth, and Towcester to be closed, thus securing considerable economy in administration. As regards the acute sick, it is agreed that the voluntary hospitals are adequate to meet the case, and arrangements have been made for a suitable payment for the services rendered. Maternity work will be concentrated at the Kettering institution in coöperation with the Kettering general hospital. This will avoid the expense of maintaining midwives at other institutions. It is also suggested that new nursery accommodation should be provided at Kettering. During the present year it is hoped to make progress with the ascertainment and classification of mental cases, and proposals embodying principles approved by dietetic experts will be brought forward for all the institutions.

In DERBYSHIRE (est. pop. 618,500) the services of specialists have been made available for the public assistance institutions, and a preliminary meeting with the voluntary hospitals committee was held on Feb. 11th, 1932, to consider the hospital provision of the county.

In WILTSHIRE (est. pop. 294,100) the steps taken towards classification are the provision of the Marlborough Children's Hospital (40 beds), the concentration of difficult male cases requiring male nurses in special wards at Salisbury, the concentration of female mentally defectives at Wilton, and the use of the male wards at Purton for juvenile idiots and imbeciles. Apart from the care of the blind, no department of treatment has yet been removed from the poor-law.

In DURHAM (est. pop. 934,100) the problem of classification is receiving attention, and the public assistance committee has been able to help the Sedgefield mental hospital by the reception of 50 male and 50 female patients, suitable for transfer, on the "house" side of two institutions.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED SEPT. 17TH, 1932

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox, 19 (last week 9); scarlet fever, 1547; diphtheria, 854; enteric fever, 95; acute pneumonia (primary or influenzal), 446; puerperal fever, 41; puerperal pyrexia, 123; cerebro-spinal fever, 25; acute polio-myelitis, 38; acute polio-encephalitis, 4; encephalitis lethargica, 7; continued fever, 1 (Tyldesley, Lancs); dysentery, 21; ophthalmia neonatorum, 81. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Sept. 20th–21st was as follows:—Small-pox, 22 under treatment (last week 19 and 2 under observation); scarlet fever, 1214; diphtheria, 1351; enteric fever, 17; measles, 301; whooping-cough, 361; puerperal fever, 22 (plus 11 babies); encephalitis lethargica, 232; poliomyelitis, 5; "other diseases," 123. At St. Margaret's Hospital there were 18 babies (plus 10 mothers) with ophthalmia neonatorum.

Deaths.—In 117 great towns, including London, there was no death from small-pox, 1 (0) from enteric fever, 7 (0) from measles, 7 (0) from scarlet fever, 21 (4) from whooping-cough, 39 (10) from diphtheria, 81 (17) from diarrhœa and enteritis under two years, and 13 (2) from influenza. The figures in parentheses are those for London itself.

Deaths from diarrhœa had not increased: Liverpool still stands highest with 13 deaths, Leeds following with 5, Birmingham with 4, Croydon, Manchester, and Leicester each 3. Barking recorded the only death from enteric fever. Three of the deaths from whooping-cough were reported from Southampton, 2 each from Sheffield, Leicester, and Grimsby.

The number of stillbirths notified during the week was 257 (corresponding to a rate of 40 per 1000 total births), including 38 in London.

NOTES, COMMENTS, AND ABSTRACTS

HRENICECTOMY IN THE TREATMENT OF PULMONARY DISEASE *

WITH AN ANALYSIS OF FIFTY-EIGHT CASES

BY LAURENCE O'SHAUGHNESSY, M.D. DURH.,
F.R.C.S. ENG.

LODGE RESEARCH SCHOLAR, ROYAL COLLEGE OF SURGEONS OF ENGLAND; LATE SENIOR MEDICAL INSPECTOR, OMDURMAN

PHRENICECTOMY is a comparatively modern pro-dure. for. although some animal experiments were one as long ago as 1890. it was not till 1911 that tuertz [1] proposed to carry out the procedure in man. n 1913 Sauerbruch [2] reported five cases in which ne operation had been done with some measure of uccess. Its effect should be paralysis of the iaphragm, but it was soon found that section of the erve frequently failed to produce this result. The ause of this remained unknown until Felix [3] and Goetze [4] in 1922 found that there was often an acces-ory phrenic nerve which pursued an independent ourse into the thorax to join the main stem.

To obtain a certain paralysis Felix proposed the operation of phrenic avulsion in which. after exposure of the nerve in the neck. it is grasped with forceps, and by traction a considerable length of it drawn out from the thorax until it finally breaks. In this way the connexion between the main trunk and its accessory branch is broken. Goetze advocated what he termed the radical operation, in which the cervical plexus is exposed and the roots of the nerve identified and cut, as well as the nerve to the subclavius and any other twigs which appear to be taking a similar course.

There are certain theoretical objections to the blind and forcible avulsion of the nerve from the thorax. It is conceivable that the nerve might be adherent to some diseased portion of the lung, and so a laceration might result. Also the tearing of other adhesions might cause hæmorrhage. In practice the danger is slight. In the event of extreme pain attending attempted avulsion it would be expedient to abandon it and carry out the operation of Goetze, but as this is technically difficult, and as excellent results are obtained by the simpler procedure, phrenic avulsion at present holds the field.

THE VALUE OF PHRENICECTOMY

Phrenicectomy has been chiefly used in pulmonary tuberculosis: in unilateral disease with a tendency to fibrosis; as a last resort in acute caseous tuberculosis; as a palliative measure in obviously incurable cases to relieve cough, vomiting, and also hæmoptysis; and as a preliminary to thoracoplasty. Many advocate it in combination with artificial pneumothorax.

Sauerbruch condemns the operation almost entirely as an individual measure, and considers that its main indication is as a preliminary to thoracoplasty. He states [5] that of 185 cases of pulmonary tuberculosis in which phrenicectomy was the sole treatment, only 15 are surviving and at work. and of these five had solitary lesions at the base. Morriston Davies,[6] who reported on 33 cases, states that 16 showed marked improvement; four of these cases were intended for thoracoplasty on account of extensive disease, but so great was their improvement after phrenicectomy that further intervention became unnecessary. Moore [7] reports that two out of ten cases are well, and five improved. Welles,[8] who reports on 271 cases, states that 174 (64 per cent.) were improved.

Of the phrenicectomies described in this report, 53 were carried out as the main therapeutic measure for pulmonary tuberculosis. It has been possible to trace 32, of whom 3 are "cured," 9 have improved, 7 are worse, and 13 have died. The series includes some recent cases which are of little value as an index of the ultimate worth of the procedure. The term "cure" is used for cases in which. in addition to general improvement, expectoration of tubercle bacilli has ceased. It is to be interpreted with caution, as one of the fatal cases spent a year in this state before a final collapse.

There have been occasional dramatic results in acute, highly febrile caseous types of tuberculosis, notably by Goetze,[9] Frisch,[10] and Brunner.[11]

All authorities are agreed that the procedure has considerable value in the treatment of such symptoms as irritative cough and vomiting. When more radical measures of pulmonary compression are not available, Davies [6] and others have had good results in cases of hæmoptysis.

Phrenicectomy can usefully be combined with artificial pneumothorax and (see Case 7 below) can be used as a preliminary measure in a patient who is too ill to bear thoracoplasty.

ITS POSSIBLE DANGERS

Sauerbruch has issued an impressive warning as to the dangers of the operation itself. He described three cases of severe hæmorrhage in which ligature of the subclavian artery was required, and two of these cases were fatal. He also mentioned the danger of air embolism and wounds of the thoracic duct. The literature contains no other record of such accidents, except that Welles [5] injured the thoracic duct in one case, but this had no serious consequences. Davies in a series of 108 cases had no fatality. The only death reported as a result of phrenicectomy, apart from purely operative complications, is by Davidson and Ledlie.[12] It was assumed that sudden compression of the base of the lung had led to general dissemination of an intense pneumococcal infection.

A SERIES OF FIFTY-EIGHT CASES

In 1926 I was working in an out-station in the Sudan where phrenicectomy appeared to be a form of collapse therapy suitable for the somewhat primitive conditions. In the absence of an X ray apparatus, air replacement or thoracoplasty was clearly impossible. Phrenicectomy merely demanded an operating theatre and some knowledge of surgical technique. The method employed was that described by Davies,[13] in which the nerve is exposed by a transverse incision as it lies on the scalenus anterior. cut, seized with artery forceps, and gradually avulsed. Anatomical variations may add difficulty—for example. the nerve at times descends vertically along the inner border of the scalene instead of pursuing its normal oblique course.

Although the patients were in many cases poor surgical material, the only local complication was a hæmatoma which delayed healing for a few days. No attempt was made to select cases suitable for cure, as even in the worst cases it was hoped to obtain some symptomatic relief. Thirty-three of the cases were followed to Jan. 31st, 1931. All these had tubercle bacilli in the sputum along with general symptoms of pulmonary tuberculosis. Five were bilateral,

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

MIDDLESEX HOSPITAL POST-GRADUATE COURSE.

MONDAY, Oct 3rd —10.15 A.M., Mr. E. W. Riches: Prostatic Obstruction with special reference to Per-urethral Operations. 11 30 A.M., Prof. Samson Wright. Some Recent Advances in Physiology and their Application to Medicine and Surgery. 2.30 P.M., Dr. G. E. Beaumont: The Modern Treatment of Pulmonary Tuberculosis (demonstration).

TUESDAY.—10.15 A M, Discussion to be introduced by Mr. E Pearce Gould: The Treatment and Results in Mal-descent of the Testicle. 11.30 A.M, Dr G. E S. Ward: Drugs in the Treatment of Heart Disease. (The course is open only to graduates of the school.)

ST. THOMAS'S HOSPITAL POST-GRADUATE COURSE.

MONDAY, Oct. 3rd.—10 A.M., Mr. W. H. C. Romanis: Diagnosis of the Acute Abdomen. 10 A.M., Dr. G. Fil [illegible] olon. 11.15 A.M., Dr. Z. [illegible] stration). 11 15 A.M., Pr [illegible] emonstration) 2 P.M., Dr [illegible] 2 P.M., Mr. C. A. R. Nitch: Surgical round.

TUESDAY.—10 A.M., Dr. H. L Tidy: Recent Work on Anæmia. 10 A.M., Mr. B. W. Williams: Recent Advances in Radiotherapy. 11.15 A.M., Dr. G. T. Hebert: Pneumothorax (demonstration). 11.15 A.M., Mr. J. M. Wyatt: Antenatal (demonstration). 2 P.M., Dr. M. A. Cassidy: Medical round. 2 P.M., Mr. B. C. Maybury: Surgical round.

WEDNESDAY.—10 A.M, Dr. J. L. Birley: Neuralgia and its Treatment. 10 A.M, Mr. R. H. O. B. Robinson: Surgery of the Chest. 11.15 A.M., Dr. H. Gardiner-Hill: Pituitary Diseases (demonstration). 11.15 A.M, Mr. Max Page: Treatment of Fractures (demonstration). 2 P.M, Mr. W. R. Bristow: Orthopædic round. 2 P.M, Dr. R. C. Jewesbury: Pædiatrics round.

THURSDAY.—10 A.M, Mr. C. A. R. Nitch: Pyelography. 10 A.M, Prof. O. L. V. de Wesselow: Diabetic Coma. 11.15 A.M, Dr. M. A. Cassidy: Orthocardiography (demonstration). 11.15 A.M., Dr. J. B. Mennell: Physicotherapeutics (demonstration). 2 P.M., Dr. J. P. Hedley: Gynæcological round. 2 P.M., Dr. J. L. Birley: Neurological round.

FRIDAY.—10 A.M., Sir Percy Sargent: Surgery of the Sympathetic Nervous System. 10 A.M., Dr. Henry Yellowlees: Diagnostic Pitfalls in Psychiatry. 11.15 A.M., Mr. P. H. Mitchiner: Treatment of Burns; Tannic Acid (demonstration). 11.15 A.M., Mr. W. G. Howarth: Throat and ear clinic. 2 P.M., Dr. J. Forest Smith: Medical round. 2 P.M., Mr. W. H. C. Romanis: Surgical round. (This course is open only to graduates of the school.)

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Oct 3rd, to SATURDAY, Oct 8th.—METROPOLITAN HOSPITAL, Kingsland-road, E. Post-graduate course in General Medicine and Surgery. All day. 10.30 A.M to 5.30 P.M. Especially suitable for general practitioners.—ST. JOHN'S HOSPITAL, Leicester-square, W.C. Afternoon course in Dermatology. Daily clinics at 2 P.M. and 6 P.M.—Lectures Tues. and Frid.—CENTRAL LONDON THROAT AND EAR HOSPITAL, Gray's Inn-road, W.C. All day Clinical Course in Diseases of the Ear, Nose, and Throat. Also Operative Surgery, Peroral Endoscopy, Pathology classes (strictly limited)—GORDON HOSPITAL, Vauxhall Bridge-road, S.W. Afternoon course in Proctology. Demonstrations, operations, and lectures.—LONDON LIGHT CLINIC, Ranelagh-road, S.W. Evening demonstrations on Physical Medicine. Mon. and Wed., 8 to 9 P.M.

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, 49, Leicester-square, W.C.

TUESDAY, Oct. 4th.—5 P.M., Dr. W. Griffith. Introductory.

THURSDAY.—5 P.M., Dr. J. M. H. MacLeod: Morphology and Histopathology of Elementary Lesions.

GRESHAM COLLEGE, Basinghall-street, E.C.2.

TUESDAY, Oct. 4th and following three days. Sir George Newman: Health and Industry.

MANCHESTER ROYAL INFIRMARY.

TUESDAY, Oct. 4th.—4.15 P.M., Dr. R. S. Paterson: Radiological Examination of the Urinary Tract.

FRIDAY.—4.15 P.M, Dr. F. R. Ferguson: Demonstration of Medical Cases.

Vacancies

For further information refer to the advertisement columns

Belgrave Hospital for Children, 1, Clapham-road, S.W.—Two H.P.'s and H S. Each at rate of £100.

Birmingham, Little Bromwich Hospital for Infectious Diseases—Jun Asst M O. £300.

Bolingbroke Hospital, Wandsworth Common, S.W.—H S. At rate of £120.

Bradford, Royal Eye and Ear Hospital.—Jun H S £150

Brentwood, High Wood Hospital for Children—Ast [illegible] £350.

Brighton Sanatorium and Infectious Disease Hospital—Jun R. M.O. At rate of £150.

NOTES, COMMENTS, AND ABSTRACTS

RENICECTOMY IN THE TREATMENT OF PULMONARY DISEASE *

WITH AN ANALYSIS OF FIFTY-EIGHT CASES

By LAURENCE O'SHAUGHNESSY, M.D. DURH.,
F.R.C.S. ENG.

LEGE RESEARCH SCHOLAR, ROYAL COLLEGE OF SURGEONS OF
NGLAND; LATE SENIOR MEDICAL INSPECTOR, OMDURMAN

PHRENICECTOMY is a comparatively modern pro-dure, for, although some animal experiments were ne as long ago as 1890, it was not till 1911 that uertz [1] proposed to carry out the procedure in man. 1913 Sauerbruch [2] reported five cases in which e operation had been done with some measure of ccess. Its effect should be paralysis of the aphragm, but it was soon found that section of the erve frequently failed to produce this result. The ause of this remained unknown until Felix [3] and oetze [4] in 1922 found that there was often an accesory phrenic nerve which pursued an independent ourse into the thorax to join the main stem.

To obtain a certain paralysis Felix proposed the peration of phrenic avulsion in which, after exposure f the nerve in the neck, it is grasped with forceps, nd by traction a considerable length of it drawn ut from the thorax until it finally breaks. In this way the connexion between the main trunk and its accessory branch is broken. Goetze advocated what he termed the radical operation, in which the cervical plexus is exposed and the roots of the nerve identified and cut, as well as the nerve to the subclavius and any other twigs which appear to be taking a similar course.

There are certain theoretical objections to the blind and forcible avulsion of the nerve from the thorax. It is conceivable that the nerve might be adherent to some diseased portion of the lung, and so a laceration might result. Also the tearing of other adhesions might cause hæmorrhage. In practice the danger is slight. In the event of extreme pain attending attempted avulsion it would be expedient to abandon it and carry out the operation of Goetze, but as this is technically difficult, and as excellent results are obtained by the simpler procedure, phrenic avulsion at present holds the field.

THE VALUE OF PHRENICECTOMY

Phrenicectomy has been chiefly used in pulmonary tuberculosis: in unilateral disease with a tendency to fibrosis; as a last resort in acute caseous tuberculosis; as a palliative measure in obviously incurable cases to relieve cough, vomiting, and also hæmoptysis; and as a preliminary to thoracoplasty. Many advocate it in combination with artificial pneumothorax.

Sauerbruch condemns the operation almost entirely as an individual measure, and considers that its main indication is as a preliminary to thoracoplasty. He states [5] that of 185 cases of pulmonary tuberculosis in which phrenicectomy was the sole treatment, only 15 are surviving and at work, and of these five had solitary lesions at the base. Morriston Davies,[6] who reported on 33 cases, states that 16 showed marked improvement; four of these cases were intended for thoracoplasty on account of extensive disease, but so great was their improvement after phrenicectomy that further intervention became unnecessary. Moore [7] reports that two out of ten cases are well, and five improved. Welles,[8] who reports on 271 cases, states that 174 (64 per cent.) were improved.

Of the phrenicectomies described in this report, 53 were carried out as the main therapeutic measure for pulmonary tuberculosis. It has been possible to trace 32, of whom 3 are "cured," 9 have improved, 7 are worse, and 13 have died. The series includes some recent cases which are of little value as an index of the ultimate worth of the procedure. The term "cure" is used for cases in which, in addition to general improvement, expectoration of tubercle bacilli has ceased. It is to be interpreted with caution, as one of the fatal cases spent a year in this state before a final collapse.

There have been occasional dramatic results in acute, highly febrile caseous types of tuberculosis, notably by Goetze,[9] Frisch,[10] and Brunner.[11]

All authorities are agreed that the procedure has considerable value in the treatment of such symptoms as irritative cough and vomiting. When more radical measures of pulmonary compression are not available, Davies [6] and others have had good results in cases of hæmoptysis.

Phrenicectomy can usefully be combined with artificial pneumothorax and (see Case 7 below) can be used as a preliminary measure in a patient who is too ill to bear thoracoplasty.

ITS POSSIBLE DANGERS

Sauerbruch has issued an impressive warning as to the dangers of the operation itself. He described three cases of severe hæmorrhage in which ligature of the subclavian artery was required, and two of these cases were fatal. He also mentioned the danger of air embolism and wounds of the thoracic duct. The literature contains no other record of such accidents, except that Welles [8] injured the thoracic duct in one case, but this had no serious consequences. Davies in a series of 108 cases had no fatality. The only death reported as a result of phrenicectomy, apart from purely operative complications, is by Davidson and Ledlie.[12] It was assumed that sudden compression of the base of the lung had led to general dissemination of an intense pneumococcal infection.

A SERIES OF FIFTY-EIGHT CASES

In 1926 I was working in an out-station in the Sudan where phrenicectomy appeared to be a form of collapse therapy suitable for the somewhat primitive conditions. In the absence of an X ray apparatus, air replacement or thoracoplasty was clearly impossible. Phrenicectomy merely demanded an operating theatre and some knowledge of surgical technique. The method employed was that described by Davies,[13] in which the nerve is exposed by a transverse incision as it lies on the scalenus anterior, cut, seized with artery forceps, and gradually avulsed. Anatomical variations may add difficulty—for example, the nerve at times descends vertically along the inner border of the scalene instead of pursuing its normal oblique course.

Although the patients were in many cases poor surgical material, the only local complication was a hæmatoma which delayed healing for a few days. No attempt was made to select cases suitable for cure, as even in the worst cases it was hoped to obtain some symptomatic relief. Thirty-three of the cases were followed to Jan. 31st, 1931. All these had tubercle bacilli in the sputum along with general symptoms of pulmonary tuberculosis. Five were bilateral,

The Chief Inspector o[illegible] int-ments for Certify[illegible] uth (Northumberland) physical signs to explain the dyspnœa. There was no evidence of pulmonary œdema or collapse, but it eemed clear that although death was inevitable the ntervention had hastened its advent.

Case 3.—This patient had extensive bilateral disease, and bilateral phrenicectomy was done, a month intervening between the two operations. As in the other cases, there was an increase in respiration-rate, and the accessory muscles of respiration came into play. In a few days the respiration-rate fell to 20, the accessory muscles no longer showed activity, and quiet respiration of ntercostal type was present. The fluoroscope showed total paralysis of the diaphragm.

The operation in this case is of too recent date for assessment as a therapeutic measure. At the same time, it is of interest to note that the respiratory, circulatory, and alimentary systems continue to work normally in the complete absence of diaphragmatic function.

Case 4.—Phrenicectomy was done for a lesion in the right upper lobe; six weeks later signs appeared in the other lung, and it was decided to paralyse the diaphragm on that side. The nerve was exposed and crushed. There was no dyspnœa, but an increase in respiration-rate. On examination with the fluoroscope a high immobile diaphragm was seen.

Six months later the left diaphragm was again working, but the right half remained motionless.

This patient appears to have derived benefit but, although his condition has improved, bacilli are still present in the sputum. Temporary paralysis can only be obtained by this method in patients without an accessory phrenic nerve.

FATAL CASES

Three of my cases illustrate the danger of phrenicectomy in patients who are acutely ill.

Case 5.—This patient was admitted complaining of severe hæmoptysis. There was evidence of consolidation of the right upper lobe, and the sputum contained tubercle bacilli. The hæmorrhage was severe, and clearly threatened life. Two attempts to induce artificial pneumothorax failed, as no free pleural space could be found.

On Dec. 23rd, 1929, as a last resort, the patient being very exhausted and having air-hunger, the right phrenic nerve was avulsed. There was no immediate dyspnœa, but half an hour later this appeared and there was marked general distress. On examination there were scattered moist râles throughout the left lung, and the expectoration of pink frothy sputum showed that acute œdema of the lung was present. The usual remedies failed, and very shortly the patient died.

The following were the *post-mortem* findings: The right pleural space was largely obliterated by adhesions, but the left pleural space was free. There was consolidation of the upper lobe of the right lung, with a small central cavity. The cavity was the size of a walnut and, on removing the contained clot, erosion into a large vessel could be seen. There were scattered areas of fibro-caseous tuberculosis in the middle and lower lobe of this lung, but no evidence of œdema. The left lung showed no evidence of tuberculosis, but was completely œdematous. No portion of the organ contained any air. The other organs appeared normal except for marked engorgement of the right heart.

No case of this type has been recorded. It is impossible to explain the relation of the phrenicectomy to the development of pulmonary œdema, but equally impossible to avoid the conclusion that it was the determining factor. The absence of œdema on the operated side is remarkable, as there was enough normal tissue in the lower lobe to allow of its recognition. It is held by Dunner[14] and others that changes in the pulmonary circulation follow phrenicectomy, and the findings in this case may have some relation to his theory. Another point of interest was the site of the hæmorrhage, which was so placed in the midst of unyielding tissue that no form of collapse therapy could possibly have influenced it.

Case 6.—This woman was admitted with advanced pulmonary tuberculosis affecting both lungs. The right lung was in worse condition than the left, and the right phrenic nerve was avulsed. The operation was done in the usual way without difficulty, and the patient exhibited no sign of distress; 24 hours later there was dyspnœa of sudden onset, and examination showed that acute œdema of the lung had supervened. The physical signs were more marked in the left lung—that is, on the non-operated side. The usual remedies were applied without avail, and the patient died some hours later. An autopsy could not be obtained.

This case serves as another example of the dangers of phrenicectomy in very advanced cases, and again raises the question of its relation to the vasomotor supply of the lung.

OTHER CASES OF INTEREST

In the following case phrenicectomy was used to prepare for thoracoplasty.

Case 7.—This patient was admitted with pulmonary tuberculosis. Clinical examination and the radiographic picture showed that the disease was almost entirely confined to the right lung. The patient was in poor condition; there was profuse expectoration and marked pyrexia. The right phrenic nerve was avulsed, with almost immediate improvement.

Six weeks later the patient had gained over a stone in weight, was apyrexial, and had much less cough. It was decided to attempt more satisfactory collapse of the lung and under spinal anæsthesia a paravertebral thoracoplasty was done, portions of the upper six ribs being removed. The patient stood the operation well and his improvement continues.

It is, of course, realised that six weeks' rest and diet would tend to improve the general condition, but it seems difficult to exclude the phrenicectomy from an important share in the transformation of a sick and emaciated patient into one sufficiently robust to withstand a major surgical operation.

Occasionally some anatomical peculiarity may lead to difficulty.

Case 8.—The nerve was found in the usual site and sectioned, but on attempting to avulse it a distinct arterial pulsation was felt. Continued avulsion was clearly dangerous, and the operation was terminated. Examination with the fluoroscope showed no paralysis of the diaphragm, so that clearly an accessory phrenic nerve existed.

This type of case has been described by Davies, who believes that the phenomenon is due to a junction between the phrenic and its accessory immediately below the subclavian vein. He has devised a small ring-shaped instrument which is passed down along the course of the nerve to sever this connexion. It seems possible, however, that some aberrant artery within the chest may be concerned, in which case it would seem wiser to divide the accessory phrenic in the neck after the manner of Goetze.

Remarks

Phrenicectomy may be a useful therapeutic measure in certain cases of pulmonary tuberculosis; it may be of value in cases of chronic empyema and in fibrosis of the lung. It can offer little help in cases of bronchiectasis, and among the rarer indications for its use may be mentioned intractable hiccup and spasm of the diaphragm.

The operation in efficient hands is not dangerous, but in those gravely ill it may have serious or even fatal sequelæ, as some of the results in the above series show.

Considered as an individual measure for the cure of pulmonary tuberculosis its results are disappointing. Phrenicectomy is, after all, the least effective method of collapse therapy, but its use is possible under primitive conditions which preclude the use of the more radical measures. Its most useful indication is probably in cases which the ordinary methods of rest and diet just fail to control, when the slight and in one the phrenicectomy was supplemented by artificial pneumothorax. As a whole the results are not encouraging, as only three "cures" are reported, and the course of the next few years may remove these from this category. At the same time some of the nine cases who have improved will probably become "cures." One or two of the results were unexpectedly good, and several cases were restored to normal health for a year or more before their final relapse.

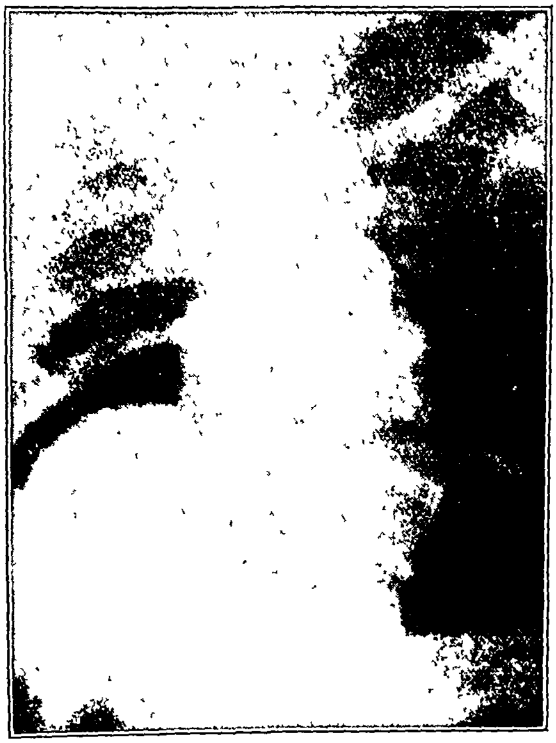
Of 23 other patients, some of whom were observed for some months, the ultimate fate is unknown. In many of these cases there was improvement in symptoms, such as irritable cough. Two cases of bronchiectasis did not benefit from phrenicectomy.

BILATERAL PHRENICECTOMY

In four cases bilateral paresis of the diaphragm was induced, and in the first of these I can give a record of the post-mortem findings a year later.

CASE 1.—A Sudanese woman of 25 years complained of cough and fever. She lived in a village on the Nile some two hundred miles south of Omdurman in a malarial district. On examination there was no splenomegaly or other evidence of malaria, but the patient was very emaciated. There was evidence of consolidation at the right apex, and scattered and persistent râles at the right base and throughout the left lung. The sputum contained tubercle bacilli.

FIG. 1



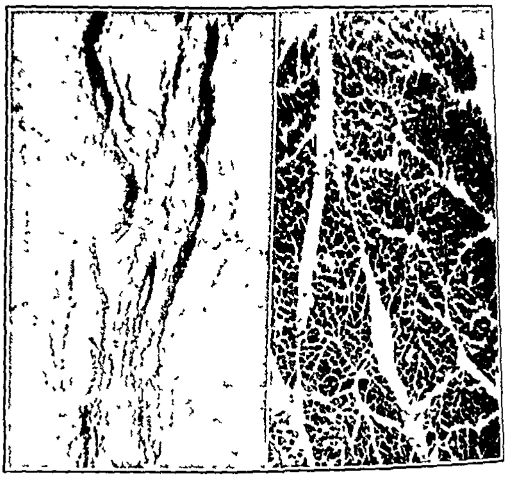
Radiogram showing high position of diaphragm after bilateral phrenicectomy (Case 1).

On August 4th, 1929, a right phrenic avulsion was done, and the fluoroscope showed a high diaphragm on the right side which exhibited paradoxical movement.

On Oct. 1st, little general improvement having occurred and signs persisting at the left base, the left phrenic nerve was avulsed. There was an immediate rise of respiration-rate to 38, the pulse became weak, and there was slight collapse. All the accessory muscles of respiration were brought into play. The acute symptoms subsided after an injection of atropine. Careful examination failed to reveal any sign of pulmonary œdema or collapse. Next day respiration was less tumultuous, and the rate had fallen to 28. The pulse was normal, and there was no alteration of physical signs in the chest.

On Oct. 15th the patient felt perfectly well and wished to leave hospital. The fluoroscope showed complete paralysis of the diaphragm (Fig. 1). The further course was one of continued improvement. She appeared to suffer no inconvenience from the loss of the activity of her diaphragm. Coughing took place normally, there was no dyspnœa even after ascending stairs, and there were no signs of impaired circulation. There was no complaint of dyspepsia, and her alimentary system functioned in every way normally. The scattered râles at both bases disappeared; the evidence of consolidation at the right apex persisted, but the encircling zone of crepitations disappeared. Two months later the sputum no longer contained tubercle bacilli and, although there had been little gain in weight, the general condition was very good. Later, her condition having further improved, she was employed as a hospital cleaner.

FIG. 2



Left: Section of diaphragm a year after phrenicectomy (Case 1).
Right: Section of normal diaphragm for comparison.

On Dec. 1st, 1930, she had a severe hæmoptysis and was readmitted to hospital. There was evidence of progressive disease in the left lung, and the lesion at the right apex appeared active. The patient became progressively worse, further hæmorrhages took place, and she died on Dec. 30th.

The following were the *post-mortem* findings: Both pleural spaces were largely obliterated by adhesions. There was extensive fibro-caseous tuberculosis throughout both lungs, with a small cavity in the right upper lobe which contained recent blood clot. There was marked atrophy of the whole diaphragm (Fig. 2). The other organs appeared normal.

It is difficult to avoid the conclusion that the course of the disease was favourably influenced by the phrenicectomy. The patient was enabled to enjoy a year of normal life, although on admission the prognosis seemed almost hopeless.

CASE 2.—Phrenicectomy was done for disease affecting the right upper lobe. There was some temporary improvement, but six months later evidence of marked disease in both lungs was found, together with tuberculosis of the larynx. The condition was clearly hopeless, but a constant irritable cough added greatly to the patient's suffering, and in the hope of alleviating this the left phrenic nerve was avulsed.

Dyspnœa and marked distress appeared as soon as the nerve was cut across, and persisted until the patient died five days later. The cough did not recur, and even voluntary coughing was impossible.

Sauerbruch has emphasised the fact that paralysis of the diaphragm, while it may allay an irritative cough, does not affect the act of voluntary coughing; in the other three cases recorded here the power of voluntary coughing was retained, but in this case it was certainly lost. There was no alteration in the

RESENT POSITION OF YMPATHECTOMY*

ELFORD, F.R.C.S. ENG., B.CHIR. CAMB.

CHESTER ROYAL INFIRMARY AND PROFESSOR OF
RGERY IN THE UNIVERSITY OF MANCHESTER

s been of late a revival of interest in the the autonomic nervous system, and the f sympathectomy is now being employed ment of many diseases. The results of interest alike to physician, surgeon, . It seems worth while, therefore, to d to attempt an estimate of the present value of the operation. The following based, in the main, on a series of 41 mies which I have performed at the Royal Infirmary and in every case I am bted to Prof. J. S. B. Stopford for his ssistance.

ssary at the outset to discuss the termin- he subject, since upon this there is ly no general agreement. The term was introduced by Winslow and implied ystem, as it was then known. Later, of the vegetative nervous system and till employed by some writers. Langley's though itself not ideal, is the one in l use at the present time. Langley the whole system as autonomic and it into the sympathetic and para- c. The former is the great thoraco-lumbar the latter the cranial and sacral outflows. tion is important as the two great outflows, sibly not so sharply defined as has been agined, are, in general, opposed to each tion.

f the various operations on the autonomic tem brings out at once the thought that lmost without exception, destructive in Langley, it is true, attempted anastomosis his researches and, more recently, Sir allance has described the experimental osis of the cervical sympathetic cord with cial and hypoglossal nerves. Beyond these loes not appear to have been any attempt at ctive surgery but the possibilities of this borne in mind in future work.

nnot avoid the thought that sympathectomy e and mutilating operation. By the operation nerely breaking one link in a chain of which ot see the beginnings, and with increasing ge the operation should become less frequent altogether disappear. Its present position t unfairly, be likened to that of thyroidectomy hthalmic goitre. If, then, our attempts aim destruction of certain portions of the autonomic n it is well, at the outset, to consider what e main functions of that system which we may to influence by ablation of the autonomic ly. These may be arranged in five main groups :—

. The control of the heart and blood-vessels.
. The control of respiration.
. The control of secretory glands.
. The control of smooth muscle of tubes and viscera.
5. The relation to visceral pain.

ch divisions are obviously incomplete, arbitrary, l tend to overlap, since a clinical result may owe its form to a combination of two or more. They are not intended to do more than to afford a convenient way of splitting up a very extensive and deeply involved subject.

The Control of the Heart and Blood-vessels

The operation of sympathectomy aims at abolishing vasoconstrictor action and it is in this group that the operation is most often performed to-day. The cases fall into two classes. On the one hand sympathectomy may be done to abolish certain noxious influences which are causing vasospasm. Here the operation has proved its value in those diseases of the blood-vessels which are characterised by continuous or intermittent spasm. On the other hand the operation may be done to produce a permanent increase in the calibre of normal and healthy vessels, so that a more abundant supply of blood may be brought to the part.

In the first class the more important lesions are Raynaud's disease, thrombo-angiitis obliterans, the vascular complications of cervical rib, and possibly retinitis pigmentosa. Of these diseases, the most clearly cut and instructive picture is afforded by the cases of cervical rib. These patients suffer from a persistent, low-grade irritation of a bundle of sympathetic fibres by friction against the rib. The result is spasm of the arteries of the limb which is evidenced by pallor and coldness of the hand. After an interval, often some twelve months, thrombosis occurs and ascends fairly rapidly up the limb to a point about the junction of the axillary and brachial arteries. Finally, gangrene of one or more fingers is seen. The picture is one of spasm followed by thrombosis and suggests that long-continued spasm of an artery will by embarrassment of the vasa vasorum lead to ill-health of the vessel wall and so to thrombosis. The histological appearances of thrombosed arteries in these cases of cervical rib correspond with those in the vessels of a fowl in which persistent spasm has been caused by repeated doses of ergot.

Many writers on the vasospastic diseases appear to regard spasm and thrombosis as quite separate conditions, and in other writings the thrombosis is envisaged as preceding the spasm. From what has been said above on the cervical rib cases it would appear that spasm and thrombosis are merely stages in the disease and that thrombosis is the result of spasm, provided always that the spasm is sufficiently severe and long-continued. The point is important because we may regard these vasospastic diseases as beginning with an area of spasm which as time goes on is encroached upon by an ever-increasing area of thrombosis. Sympathectomy can cure these cases only by abolishing spasm, but can have no conceivable effect on a vessel which is already choked by an organised thrombus ; hence if the operation is to succeed it must be done reasonably early in the course of the disease. This contention is fully borne out by the results we have obtained from sympathectomy in these diseases. Those cases in which spasm is evident give satisfactory and even brilliant results, but those cases in which thrombosis is marked, and especially those in which gangrene is threatened or actually present, give results which can only be regarded as disappointing. For example, the results in the more advanced cases of thrombo-angiitis obliterans are poor.

There is, fortunately, an easy method of discovering the relative amounts of spasm and thrombosis in any given case and this question will be discussed later.

---

b tract of a presidential address to the Manchester Medical ty on Oct. 5th.

additional rest may incline the balance towards the healing side.

Phrenicectomy is of undoubted value in controlling symptoms caused by adhesions in the region of the diaphragm, and is a useful preliminary to the operation of thoracoplasty.

COMPLEMENT-FIXATION TEST IN VULVO-VAGINITIS OF CHILDREN.

THE diagnosis of acute gonorrhœa in childhood is usually a matter of little difficulty. Not only are gonococci easily demonstrable in the direct smear, but the clinical picture is pathognomonic—dusky red coloration of the genital mucous membranes with eczematous crusting of the surrounding skin and profuse sticky yellow or green pus oozing from the vagina. The urethral orifice may also be œdematous and exude pus, and there is frequently a sharply demarcated reddened area around the anus. In the more chronic cases, however—and the disease is characterised by its chronicity—it may be much harder to distinguish between a vulvo-vaginitis of gonococcal origin and one that is due to other causes. The clinical picture is much less typical than that of the acute case, and the great number and variety of organisms present in smears and cultures may make identification of the gonococcus an uncertain procedure. It is therefore in the chronic case that additional aids to diagnosis would be appreciated. The complement-fixation test of Müller and Oppenheim is remarkably specific in the gonorrhœa of adults; T. E. Osmond and J. O. Oliver [1] in reporting 5000 tests found only 0·6 per cent. false positives and a high percentage of positives in all except very early cases. The value of the test in children is less definitely established, though in this country D. K. Brown [2] has reported favourably in a small series of cases. Alfred Fessler [3] has now examined the results of the test in a well-controlled series of cases, ranging in age from 2 months to 14 years, the majority being between 4 and 8 years old. He divides them into four groups: (I.) 50 control cases, free from vulvo-vaginitis; (II.) 20 cases with non-gonorrhœal vulvo-vaginitis; (III.) 50 cases in which gonococci were present in the vaginal secretion; and (IV.) 23 "follow-up" cases of gonorrhœa which had been treated and cured of their condition at least two years previously. Of the control groups (I.) and (II.), group (I.) showed 47 negatives and 3 weak positives, and Group II. 19 negatives and 1 weak positive. Group III. gave 31 positives, of which 13 were medium or weak positives. In Group IV. all cases that had been cured for more than three years gave negative results, while the remaining 11 cases showed 2 positives, 2 weak positives, and 7 negatives. Fessler concludes that the test is definitely valuable in the diagnosis of gonorrhœa in children, in spite of the relatively large number of weak positive reactions that occurred. The explanation of the difference between the value of this test in adults and in children may be that in children the disease tends to remain both localised and resistant to treatment, and thus the formation of antibodies is relatively poor. The author agrees with the majority of observers in regarding treatment by stock vaccines as ineffective.

A BOGUS SALESMAN

WE are informed by Messrs. S. Maw, Son and Sons, Ltd., of Aldersgate-street, E.C., that doctors in London and the suburbs are receiving visits from a man who purports, without authority, to represent that firm in the capacity of a travelling salesman. The man's methods are to present a card bearing the name of the firm and to take an order for medical sundries, such as labels or charts, and collect payment. He then departs and no more is heard of him. So far, we are informed, the suggested amount seems to be up to £1, but it is of course possible that he may attempt to obtain larger sums. Up to the present the field of his activities has included Shepherd's Bush, Norbury, Fulham, Whitechapel, and Acton, and he has given his name variously as O'Connor, O'Gorman, Collins, and Hayes. He is said to speak with an Irish accent.

Practitioners who receive visits from the man to whom this warning relates should be on their guard and, for the protection of others, may consider a discreet communication with the police.

REMOVABLE POCKETS

Dr. Percy Edgelow has demonstrated to us a pocket which he has devised for coat and trousers, capable of being removed, cleansed, and disinfected by boiling or otherwise, and replaced at will. Its construction is simple. Slotted tapes of fabric are attached round the edges of the entrance into the pocket itself and near the edges of the garment entrance for the pocket. A narrow strip of fabric binds the corresponding edges together by simply lacing one to the other. Dr. Edgelow has worn such pockets for some months and finds them holeproof and otherwise satisfactory. "The dirty and infected condition of the ordinary fixed pockets of garments is," he remarks, "a reflection on the progress of hygiene." And practical hygienists will agree with him.

SURBITON HOSPITAL.—Cricket matches played annually for the benefit of the hospital for the last five years between an All-England team, and a team of 18 selected from the Surbiton cricket clubs, have produced over £3000. The money has been used for the purchase of Hill Manor, Surbiton Hill, for the provision of a larger hospital.

Births, Marriages, and Deaths

MARRIAGES

COSTOBADIE—WILKINSON.—On Sept. 23rd, at the Huguenot Chapel, Canterbury Cathedral, Lionel Palliser Costobadie, M.D., F.R.C.S., of Brookfield, Folkestone, to Aileen, only daughter of Mr. and Mrs. G. B. Wilkinson, of Smallhythe, Tenterden, and Folkestone.

MACKIN Sept. 20th, at the Congregati , Dr. Alistair MacKinnon to Dr.

ORR—CARMICHAEL.—On Sept. 7th, at Windsor Presbyterian Church, Belfast, John Washington Orr, M.D., B.Sc. Belf., to Nora Margaret, second daughter of Mr. and Mrs. D. J. Carmichael, of 7, Harberton-drive, Balmoral, Belfast.

POPE—GALE.—On Sept. 24th, at Milland Church, Samuel Pope, M.D., to Charlotte Hope, youngest daughter of the late Ernest Sewell Gale, F.R.I.B.A., and Mrs. Gale, of Tile Cottage, Liphook, Hampshire.

ROSS—CUTHBERT.—On Sept. 20th, at Tron Church, Edinburgh, William Fraser Ross to Margaret Jane Mudie Cuthbert, M.A., M.B., Ch.B., Sheen-road, Richmond, Surrey.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

tion. This sudden and complete cessation of tempts one, at first, to think that an afferent way has been abolished, but the true explanation doubt that given by Lewis. The pain of vascular se is due to the retention in the tissues of the ucts of muscular action and when these are pt away by the improved circulation the pain es. This contention is in accord with our observa- that in severe cases of thrombo-angiitis obliterans much thrombosis the pain and claudication may be lost because the sympathectomy has not given fficiently marked improvement in the circulation.

ome Italian surgeons have reported the value of pathectomy of the renal pedicle in cases of pain the kidney due to no ascertainable cause, and in s country J. B. Oldham has reported a number of ourable results.

Resection of the presacral nerve has been practised ry extensively by French and Italian surgeons for e relief of pain due to various pelvic lesions. These lude dysmenorrhœa and inoperable growths not volving the sacral plexus. The resection of the esacral nerve has been done on many occasions in is country, but the operation has, to say the least, t been received with the enthusiasm which marks ntinental writings. Although the results have casionally been very good and even dramatic, the peration must be regarded at present as experimental. uch work will need to be done before its value can e established; neither its rationale nor its precise dications are as yet clear.

Lastly, it is much to be regretted that the claims hich were made for sympathectomy in the spastic have not been established. In this connexion made many observations on the muscular condition of the limbs in sympathectomised patients. We have never encountered any suggestion of altered function, nor have we been able to note by ordinary clinical tests any difference from the normal in these patients.

Preliminary Tests of the Value of the Operation

In the majority of the diseases in which sympathectomy is being considered as a line of treatment, it is possible to obtain an exact forecast of the extent to which the operation will succeed. In cases in which the objective is to produce vasodilatation, the degree to which this change is possible can be ascertained beforehand either by the induction of fever or by nerve block. The former method depends upon the induction of fever by the injection of foreign proteins; the latter consists in a temporary interruption of sympathetic fibres by either spinal anæsthesia or local nerve block. These methods have been described by several writers and they should, in one or other form, be always done before deciding on sympathectomy. The observations on surface temperature will yield an accurate measure of the extent to which the disease is due to spasm and the extent to which collateral vessels may be enlarged by sympathectomy.

Similarly, in cases of Hirschsprung's disease, a barium enema given under spinal anæsthesia will give valuable information as to the possibility of shrinkage in the affected bowel after sympathectomy.

The Type of Operation

The present account is not concerned with the technique of the operation, but the type of procedure calls for some mention. In diseases of the extremities the perivascular sympathectomy should not be done because, valuable as it has been in pointing the way, it is in these cases incomplete and anatomically unsound. It is, however, retained in some abdominal sympathectomies—e.g., of the renal and inferior mesenteric arteries—though here it is open to the objection that it destroys sympathetic and parasympathetic alike. Ramisectomy, as inflicting the minimum of damage, would be the ideal operation but for the fact that the anatomy of the autonomic system is very variable and our knowledge of it far from complete. It is best, therefore, to do too much rather than too little and, at present, the extensive removal of cord and ganglia gives the best chance of success.

The Permanency of the Results

It is very commonly objected that the results of sympathectomy are merely temporary and that relapse is common. That this is true of some cases there can be no doubt, but the explanation will be found to lie in the inadequate removal of tissue. For example, perivascular sympathectomy is quite inadequate in the limbs. But the main reason for relapses and incomplete results lies in the very complicated and variable anatomy of the ganglia and rami.

In this respect there is a difference between the upper and lower extremities. From our experience we believe that a radical removal of the lumbar sympathetic cords, together with the second, third, and fourth ganglia on each side, gives a complete and permanent result in the lower extremities. In the upper limb the results are not so consistently good and complete. This is due to the very great variation in the arrangement of the lowest cervical and first two dorsal ganglia with their associated rami. Drawings made from dissections of 25 subjects by Dr. Donal Sheehan in the Department of Anatomy at Manchester show a variability so extreme that scarcely two subjects are alike. The cause of failure and relapse in the upper limb is, beyond doubt, inadequate operative removal.

It is much to be desired that all material removed by operation be very carefully examined. Reports on this aspect of the subject are few and scanty. Fibrosis of the cord and ganglia, with degenerative changes in the cells, have been described. In a large series we have found these same changes, but when these specimens are contrasted with a series of presumably normal cords and ganglia the differences are not great. It is evident that the normal appearances show great variation, particularly in the amount of fibrous tissue, and further work on the minute structure of the human autonomic system, especially in relation to the effect of age, is much needed. Even if these changes in the cords removed at operation be established, we are still in the dark as to what is causing them, and in this respect the recent work on the discovery of a higher controlling centre for the autonomic system is of great and hopeful significance.

Hesse gives a very full account of the many conditions and diseases for which sympathectomy has been practised up to the year 1930. To read the number and variety of these adventures is to realise why sympathectomy is suspect and has a past to be lived down. It is most earnestly to be hoped that the present revival of the operation will be based on sound anatomical and physiological foundations. If this be granted, sympathectomy will certainly take its place as a distinct advance in the treatment of some chronic and hitherto intractable diseases. It will find its place the sooner if it is done early in the history of the case. It should not, as is too often the case at present, be regarded as the last and desperate resource.

Whilst sympathectomy is amply justifying itself in the vasospastic diseases, its history has not been so fortunate when we come to the heart itself. On the assumption that angina pectoris depends upon spasm and occlusion of the coronary arteries its treatment by sympathectomy would be rational, in that it is based on the same reasons as weigh with us in claudication of the limbs. The operation has, however, given such variable and often [illegible], that it has not found favour wi[illegible]. The difficulties are great and arise mainly from the complex pathways of supply and from the uncertainty as to how far the coronary vessels are narrowed by spasm or choked by atheroma. For this latter condition, always the more probable, sympathectomy can do nothing.

The second class of case in which sympathectomy affords good hope of relief or cure comprises many and varied diseases. The factor common to all is that good may be done by producing a vasodilatation and so bringing more blood to the part. This class includes conditions such as chronic ulcers, neuroparalytic keratitis, and the blue chilblained limbs of anterior poliomyelitis.

There is one type of case in which we have found sympathectomy to yield very good results. The patient, usually a young woman, suffers from poor circulation, particularly in the lower extremities. Such a condition is, of course, common and is usually of no great moment, but in a few instances the condition is so extreme as to cause persistent weakness and aching of the limbs with chilblains and indolent ulcers, so that the patient is badly crippled. We have found that lumbar sympathectomy will give excellent results in these cases; the patients are restored to a full active life.

Another direction in which the operation may have a promising future is in the treatment of certain cases of chronic infective (rheumatoid) arthritis. Reported cases tend to show that in those [illegible] benefit distinctly by the temporary [illegible] caused by the application of heat or counter-irritants, the operation of [illegible] of much use.

There is also t[illegible] cases known as scleroderma and sclerodactyly. In our experience sympathectomy is of real value in these conditions. It is astonishing to see how quickly the skin begins to return to a loose, supple, and natural state. But it is essential that the operation be done early before very gross changes have set in. We have found the result disappointing where advanced changes are present in the skin with contractured fingers deformed by persistent ulceration of the pulp.

The Control of Respiration

Sympathectomy has been very extensively done in the past for asthma and in view of the spasm seen in many cases the procedure would appear to be reasonable and hopeful. Unfortunately the results have not proved good and a survey of the literature leads one to the conclusion that the operation must, in the present state of our knowledge, be regarded as not worth while.

The Control of Secretory Glands

One of the great functions of the autonomic nervous system is to control the glands, both of internal and external secretion. The power to regulate the secretion of a gland should be of great help in the treatment of some diseases, but unfortunately it has not been possible to use this weapon, save in a very few cases.

Sympathectomy for hyperthyroidism has been done very extensively but has deservedly dropped out of use; obviously it is based on false pathology. [illegible] Hesse reports success from sympathectomy in cases of profuse salivation due to over-activity of the parotid gland.

At present the main scope of sympathectomy in this group appears to be in the treatment of excessive sweating. Some cases of cervical rib show this symptom and it is interesting to note that it disappears at once when the frictional irritation of sympathetic fibres is brought to an end by removal of the rib. In some cases of the Raynaud type sweating may cause serious inconvenience, especially in the lower extremity.

I have had a male patient with attacks of coldness and pallor in both feet in whom the amount of sweat gave rise to serious disability; the skin of the soles became sodden, [illegible] that the man was confined to [illegible] at once stopped the sweating; [illegible] skin was normal; the man is now doing his full work.

Control of Smooth Muscle of Tubes and Viscera

Broadly speaking the parasympathetic is the motor and the sympathetic the inhibitory nerve for the smooth muscle of the body.

The action of the vagi on the stomach has long been known and some surgeons have attempted the treatment of gastric ulceration by section of these nerves. Good results have been claimed and, in this respect, J. Beattie's observation that stimulation of a higher centre in the floor of the third ventricle produces increased motility of the stomach and increases acidity of its juice is of great interest. Some of Beattie's animals died from peritonitis due to the perforation of acute ulcers and this observation will have to be taken into account in the vexed question of the ætiology of gastric and duodenal ulceration.

It has long seemed probable that conditions such as "congenital" pyloric stenosis and "congenital" megacolon owe their origin to sympathetic and parasympathetic imbalance. The treatment of Hirschsprung's disease by sympathectomy is giving good results, provided it is done at an early age before gross and irrecoverable changes have taken place in the wall of the gut.

It is an easy step from the treatment of megacolon to that of obstinate constipation. R. H. Boggon, working under Sir Percy Sargent, has recently reported five cases in which good results have followed sympathectomy and has given a list of indications for the operation. It is, of course, a common observation that after a lumbar sympathectomy has been done for some other condition the bowel action will show some improvement.

J. R. Learmonth has recently drawn attention to the use of sympathectomy in certain lesions of the urinary bladder. The sympathetic supply to the bladder which passes along the presacral nerve is inhibitory or "filling" in its action, whilst the parasympathetic supply, derived from the sacral routes, is motor or "emptying" in function. In some lesions, low down in the cord, imbalance results and causes retention. This condition has received the name of "the cord bladder" and such cases have been successfully treated by resection of the presacral nerve.

The Relation to Visceral Pain

Relief of pain is often one of the most striking and gratifying results of sympathectomy. Patients who are worn out with the pain of vasospastic diseases usually experience complete relief and will often fall into an unbroken sleep for many hours after the

20 of the powder—a level teaspoonful—to an ounce varm water). This usually caused no additional pain, act, when coagulation commenced, what pain there disappeared; if, by chance, the patient did complain, eaker solution was used at the beginning. When a white gulum formed, gauze soaked in the solution was laid over burn and a bandage applied. Next day the gauze was stened with the solution and carefully removed, but re the lowest layer was firmly adherent it was in position. More of the solution was then painted and allowed to dry before the dressing was replaced. the third or fourth day the crust was reinforced painting on collodion mixed with an equal part tannic acid in ether; if the crust was not dry this sometimes painful. On the fifth day this was repeated, in about a fortnight the crust peeled off. If a piece of crust was separated, as happened not infrequently even en great care was taken, we covered the small raw area h a single layer of gauze and painted it over with the lodion mixture.

We believe this third method will be found to have widest application. No anæsthetic is needed, le pain is felt, and it has all the advantages of the nic acid treatment of severe burns in the wards. suspending the use of the water solution on the rd day, and by strengthening the crust with collo- on, the chance of the affected area becoming moist ien covered with a dressing is considerably minished. To what this effect is due is an interesting oblem. When the crust is covered with collodion aporation is diminished, and one would expect more softening than before. In our cases the opposite has occurred, which leaves one to doubt whether evaporation from the surface is as important a factor as was at one time thought. A mild degree of sepsis arising from the edge of the crust where it is rubbed by a dressing and in contact with skin which cannot be quite sterile may perhaps be the sole cause of this softening. When a layer of collodion is added to the crust itself and the skin around it, more protection is afforded at the edge, the dressing slides more easily over its surface, mechanical damage to the crust is less likely to occur, and organisms are thus unable to gain a hold.

For the treatment of small burns at home the collodion can be omitted, and it is only necessary to cut away the blisters with a clean pair of scissors, to apply a dressing soaked with tannic acid in water, and to change this daily for the first few days. The moist dressing may be changed for a dry one on the second day if all the raw area is covered by a crust; if a piece of the crust is torn off by accident a moist tannic acid dressing may have to be replaced for 24 hours.

ADDITIONAL CONSIDERATIONS

1. In the *first-aid treatment* of burns and scalds it seems probable that much benefit might result if aqueous tannic acid (5 per cent.) were used in every case. The only materials needed would be a small packet of powder (grs. 20) from which a fresh solution is prepared with the greatest ease at a moment's notice, and a strip of clean gauze. Pain would be relieved, the formation of a coagulum ensured without delay, and the chances of sepsis reduced.

The use of oily substances as first-aid treatment is to be deprecated, because they have to be cleaned away under an anæsthetic before tannic acid is applied. It is said that they interfere with subsequent tannic acid treatment, but in our series carron oil, butter, liquid paraffin, and machine oil were used by different patients before they came to hospital, and in every case, after thorough cleansing (under anæsthesia) with ether, in which these oily substances *are soluble*, the tannic acid formed a satisfactory coagulum.

2. *Delay between the accident and commencement of treatment* is said to influence adversely the action of tannic acid, but in our series this factor has not been prominent; after delays of from three to nine days the burns are always infected, but with thorough cleansing under general anæsthesia, and the use of tannic acid, many painful dressings have been eliminated and healing has been rapid.

3. The *degree of the burn* or scald is a factor of importance. First degree burns—showing only redness of the skin, using Dupuytren's classification—may need no special dressing. Burns of the second degree, when a blister is formed without involving the dermis, or of the third degree, with partial destruction of the dermis (leaving the hair follicles intact)—the commonest types of burns and scalds—any one of the methods here described may be used, the last being most often suitable. Those of the fourth degree, with the whole dermis destroyed, may be treated in the same way if small enough to be dealt with in the out-patient department; but in this case treatment is prolonged because a granulating surface is left when the crust comes off at the end of two or three weeks, and this has to be covered in course of time by epithelium growing from its edge.

4. *Local anæsthesia* was employed in nine cases, all small burns 4×3 in. in diameter. 4 per cent. novocain was either injected into the blister, painted on the raw surface, or infiltrated around the burn. It was useful in old persons, and when general anæsthesia was refused when small burns were very dirty and needed thorough cleansing.

5. A *scrubbing brush* is often recommended for cleaning up the burned area. We used one in our earlier cases but have since given it up, as we found to our surprise that those cases healed the quickest which were treated under local anæsthesia, when no scrubbing brush had been used in consideration for the feelings of the patient. Much bleeding, such as follows vigorous scrubbing, tends to raise the coagulum above the surface of the burn with the collection of fluid between the two.

6. It is important that a *fresh solution* of tannic acid in water should be made up every time it is required, as reduction to gallic acid occurs after a few days.

7. *Solutions stronger than 5 per cent.* are said to irritate the skin and even to cause sloughing in delicate tissues. We find that a 5 per cent. solution has no injurious effect on the burn itself or on the skin round it.

8. We now use a *soft camel-hair brush* ¾-inch wide instead of a spray. If bleeding or serous exudation be free and a spray is used, it is the surface of the blood or serum which is coagulated and fluid collects beneath. With a brush such exudates are wiped away, allowing the tannic acid direct access to the surface of the burn. One brush lasts a long while—e.g., we have used only two for all our cases and both remain in good condition. After use they are cleaned in ether soap and boiled, stored dry, and before use boiled again. With burns and scalds of the face, the eyes and nostrils have to be carefully protected from tannic acid, and a brush is found to be more convenient than a spray.

9. *Adequate splinting* is almost invariably needed for burns involving hands, elbows, and ankles. A plaster-of-Paris bandage, folded on itself to form a "slab" and fixed with a bandage, is easily applied to limbs of any size or shape.

10. A great deal of the success of treatment depends on the care with which the *second dressing* is done. With the larger burns half an hour or more

THE TREATMENT OF BURNS IN OUT-PATIENTS WITH REINFORCED TANNIC ACID DRESSINGS

BY J. H. HUNT, B.M. OXF.

AND

P. G. SCOTT, B.CHIR. CAMB.

HOUSE SURGEONS, ST. BARTHOLOMEW'S HOSPITAL

IN the out-patient department of a hospital, and also in general practice, burns and scalds frequently prove difficult and disappointing to treat. Regarded at first so often as comparatively trivial injuries, they are found to require painful daily dressings, which cause considerable distress and anxiety to the patient. This *pain* and the almost inevitable *sepsis*—with extra damage to tissues, delayed healing, and ugly scarring—are the factors which make small burns so formidable, especially in young children; much relief should be felt by patients, doctors, and nurses alike if a method of treatment could be found in which these two factors are reduced to a minimum.

The excellent articles of E. C. Davidson, W. C. Wilson, and others, to which references are given at the end of this paper, clearly set forth the principles involved and the methods employed in the tannic acid treatment of burns which are serious enough for the patient to be admitted into hospital. Little, however, has been written on the application of this method to the treatment of out-patients, and the results recorded are not always encouraging.

For the treatment of burns in general, tannic acid possesses several outstanding advantages over other substances. As a powder it is easily stored or carried about. It dissolves readily in water. It is excellent as a first-aid dressing, since it diminishes pain and is antiseptic. When the patient can be confined to bed, Davidson's treatment consists in thorough cleansing of the burned area; cutting away all the blistered skin; the application of gauze dressings soaked in a solution of tannic acid in water; the removal of these dressings after 24 hours and exposure of the tanned surface to air and radiant heat. A modification of Davidson's method was introduced by Beck and Powers, who used a spray for applying the solution, the spraying being repeated at intervals during the first 24 hours. The crust forms a protective covering for the burned area, and in it are fixed those products of tissue-breakdown to the absorption of which the toxæmia following burns is due. Pain is relieved, sepsis eliminated, and healing takes place quickly; in ten days to a fortnight the crust peels off, exposing new skin beneath. It has been found that if the crust is covered with a bandage and not exposed to the air it soon becomes moist and soft, the toxins are dissolved out of its deep surface and absorbed, and sepsis usually follows.

With a small burn a single preliminary dressing is needed and the patient has to be sent home. Here lies the difficulty; to form a thick crust at a single dressing and to prevent this crust becoming soft under a bandage. Reinforcement of the crust suggested itself as a possible way out of the difficulty.

METHODS TRIED

Over a period of six months in the out-patient department of St. Bartholomew's Hospital, 63 cases of minor burns have been treated with reinforced tannic acid dressings, the progress of each case being closely followed.

Three modifications of the method have been tried, as it was hard to foretell the treatment most suitable for different types of patients, of different ages and occupations, with burns and scalds produced in different ways, of different degrees of severity and extent, in different parts of the body, and seen at different periods after the accident. The oldest patient in our series was a woman of 73, and the youngest a child of 18 months; the burns have been situated on the face, shoulders, chest, back, arms, legs, hands, and feet, and have varied in size from 2 × 1½ in. to 12 × 6 in. The majority have been scalds from boiling water, milk, or tea; but high-voltage electric current, molten wax, hydrofluoric acid, salad dressing, and boiling beer have entered the list. The interval between the time of the accident and the commencement of treatment varied from half an hour to ten days.

The three methods we tried were: (*a*) tannic acid in ether reinforced with gauze; (*b*) tannic acid in ether reinforced with gauze and collodion; (*c*) tannic acid in water reinforced (on the third day) with collodion.

(*a*) *Tannic acid in ether reinforced with gauze.*—Under general or local anæsthesia, the area around the burn and the burned surface itself were cleaned with spirit, blistered skin cut away, and a saturated solution of tannic acid in ether (2½ per cent.) painted on with a soft camel-hair brush until a white coagulum formed. A thin layer of gauze was then laid over this so as to overlap its edges, covered with more gauze soaked in the tannic acid solution, and a bandage applied. Two days later the gauze was lifted off, leaving one layer still in contact with the raw area; the edge of this lowest layer was usually black and hard, its centre still yellow and moist. Strips of gauze, soaked in the same solution, were again laid on, the patient being warned that this would be painful for a moment or two. On the fourth and fifth days, if the centre of the gauze was still moist, more of the solution was again used; if dry, only a spirit dressing was needed, and the patient did not attend for a week. On the 12th to the 16th day the layer of gauze peeled off without pain, exposing new pink skin underneath. This was hardened with spirit for two days before all dressings were discarded.

We find this method excellent when the burns are extensive and dirty, when oil or grease has been used as a first-aid dressing, or when there has been a delay of more than 24 hours after the accident, for these conditions necessitate thorough cleansing with ether and ether soap, which must be done under an anæsthetic.

(*b*) *Tannic acid in ether, reinforced with gauze and collodion.*—Under local or general anæsthesia the burned area and its surroundings were cleaned as before, and painted with tannic acid in ether until a coagulum began to form. To the tannic acid in ether an equal quantity of collodion was then added and the painting continued. Over the coagulum a thin layer of gauze was laid, fixed in position with more of the solution, and, when this was dry, covered with a dressing. Next day all dressings were removed except the lowest layer of gauze, which was now adherent; and more of the mixture painted on—painful for a moment. On the third day this was repeated, usually without pain. After about 14 days the reinforced crust peeled off, leaving a dry, healed surface.

This second method is satisfactory in clean cases where other circumstances call for an anæsthetic—e.g., in nervous patients and young children. The extra strong crust resulting from the combined effect of gauze and collodion is especially suitable in children, who are always restless and in whom adequate splintage is difficult.

(*c*) *Tannic acid in water reinforced, on the third day, with collodion.*—Without an anæsthetic, the skin around the burn was cleaned with spirit, avoiding the raw area, blisters cut away, and the burn itself carefully painted with a fresh 5 per cent. solution of tannic acid in water (grs. 20 of the powder—a level teaspoonful—to an ounce of warm water). This usually caused no additional pain, in fact, when coagulation commenced, what pain there was disappeared; if, by chance, the patient did complain, a weaker solution was used at the beginning. When a white coagulum formed. gauze soaked in the solution was laid over the burn and a bandage applied. Next day the gauze was moistened with the solution and carefully removed, but where the lowest layer was firmly adherent it was left in position. More of the solution was then painted on and allowed to dry before the dressing was replaced. On the third or fourth day the crust was reinforced by painting on collodion mixed with an equal part of tannic acid in ether; if the crust was not dry this was sometimes painful. On the fifth day this was repeated, and in about a fortnight the crust peeled off. If a piece of the crust was separated, as happened not infrequently even when great care was taken, we covered the small raw area with a single layer of gauze and painted it over with the collodion mixture.

We believe this third method will be found to have the widest application. No anæsthetic is needed. little pain is felt, and it has all the advantages of the tannic acid treatment of severe burns in the wards. By suspending the use of the water solution on the third day, and by strengthening the crust with collodion, the chance of the affected area becoming moist when covered with a dressing is considerably diminished. To what this effect is due is an interesting problem. When the crust is covered with collodion evaporation is diminished, and one would expect more softening than before. In our cases the opposite has occurred, which leaves one to doubt whether evaporation from the surface is as important a factor as was at one time thought. A mild degree of sepsis arising from the edge of the crust where it is rubbed by a dressing and in contact with skin which cannot be quite sterile may perhaps be the sole cause of this softening. When a layer of collodion is added to the crust itself and the skin around it, more protection is afforded at the edge, the dressing slides more easily over its surface, mechanical damage to the crust is less likely to occur, and organisms are thus unable to gain a hold.

For the treatment of small burns at home the collodion can be omitted, and it is only necessary to cut away the blisters with a clean pair of scissors, to apply a dressing soaked with tannic acid in water, and to change this daily for the first few days. The moist dressing may be changed for a dry one on the second day if all the raw area is covered by a crust; if a piece of the crust is torn off by accident a moist tannic acid dressing may have to be replaced for 24 hours.

ADDITIONAL CONSIDERATIONS

1. In the *first-aid treatment* of burns and scalds it seems probable that much benefit might result if aqueous tannic acid (5 per cent.) were used in every case. The only materials needed would be a small packet of powder (grs. 20) from which a fresh solution is prepared with the greatest ease at a moment's notice, and a strip of clean gauze. Pain would be relieved, the formation of a coagulum ensured without delay, and the chances of sepsis reduced.

The use of oily substances as first-aid treatment is to be deprecated, because they have to be cleaned away under an anæsthetic before tannic acid is applied. It is said that they interfere with subsequent tannic acid treatment, but in our series carron oil, butter, liquid paraffin, and machine oil were used by different patients before they came to hospital, and in every case, after thorough cleansing (under anæsthesia) with ether, in which these oily substances are soluble, the tannic acid formed a satisfactory coagulum.

2. *Delay between the accident and commencement of treatment* is said to influence adversely the action of tannic acid, but in our series this factor has not been prominent; after delays of from three to nine days the burns are always infected, but with thorough cleansing under general anæsthesia, and the use of tannic acid, many painful dressings have been eliminated and healing has been rapid.

3. The *degree of the burn* or scald is a factor of importance. First degree burns—showing only redness of the skin, using Dupuytren's classification—may need no special dressing. Burns of the second degree, when a blister is formed without involving the dermis, or of the third degree, with partial destruction of the dermis (leaving the hair follicles intact)—the commonest types of burns and scalds—any one of the methods here described may be used, the last being most often suitable. Those of the fourth degree, with the whole dermis destroyed, may be treated in the same way if small enough to be dealt with in the out-patient department; but in this case treatment is prolonged because a granulating surface is left when the crust comes off at the end of two or three weeks, and this has to be covered in course of time by epithelium growing from its edge.

4. *Local anæsthesia* was employed in nine cases, all small burns 4×3 in. in diameter. 4 per cent. novocain was either injected into the blister, painted on the raw surface, or infiltrated around the burn. It was useful in old persons, and when general anæsthesia was refused when small burns were very dirty and needed thorough cleansing.

5. A *scrubbing brush* is often recommended for cleaning up the burned area. We used one in our earlier cases but have since given it up, as we found to our surprise that those cases healed the quickest which were treated under local anæsthesia, when no scrubbing brush had been used in consideration for the feelings of the patient. Much bleeding, such as follows vigorous scrubbing, tends to raise the coagulum above the surface of the burn with the collection of fluid between the two.

6. It is important that a *fresh solution* of tannic acid in water should be made up every time it is required, as reduction to gallic acid occurs after a few days.

7. *Solutions stronger than 5 per cent.* are said to irritate the skin and even to cause sloughing in delicate tissues. We find that a 5 per cent. solution has no injurious effect on the burn itself or on the skin round it.

8. We now use a *soft camel-hair brush* ¾-inch wide instead of a spray. If bleeding or serous exudation be free and a spray is used, it is the surface of the blood or serum which is coagulated and fluid collects beneath. With a brush such exudates are wiped away, allowing the tannic acid direct access to the surface of the burn. One brush lasts a long while—e.g., we have used only two for all our cases and both remain in good condition. After use they are cleaned in ether soap and boiled, stored dry, and before use boiled again. With burns and scalds of the face, the eyes and nostrils have to be carefully protected from tannic acid, and a brush is found to be more convenient than a spray.

9. *Adequate splinting* is almost invariably needed for burns involving hands, elbows, and ankles. A plaster-of-Paris bandage, folded on itself to form a "slab" and fixed with a bandage, is easily applied to limbs of any size or shape.

10. A great deal of the success of treatment depends on the care with which the *second dressing* is done. With the larger burns half an hour or more

may be required to remove the gauze, layer by layer, and even thread by thread, when it sticks to the crust. If handling be rough this crust may be pulled right off in places, and every precaution should be taken to avoid this. Rather than run this risk it is often better to leave the lowest layer of gauze in position and to treat it thereafter as part of the crust.

SUMMARY

In this series of 63 consecutive cases a modification of the recognised tannic acid method has been used for the out-patient treatment of burns and scalds.

If the crust formed by the recognised method is covered with a dressing and bandage it tends to soften, become septic, and detached. The difficulty has been overcome in this series of cases by reinforcement of the crust, either with a thin layer of gauze, gauze and collodion, or collodion alone. The results have been very encouraging, especially in those burns of the face and hands which often give so much trouble. Details of the three methods are given.

In the majority of second and third degree burns the method of choice, and one that reduces pain and sepsis to a minimum, is to paint the burned area with a 5 per cent. solution of tannic acid in water, and apply a dressing soaked in the same solution. No anæsthetic is required. Next day when the dressing is removed the burn will be found covered with a thin brown crust, and the dressing is repeated. On the third and fourth day this crust is reinforced with collodion. The surface then remains hard and dry and the crust separates towards the end of the second week, exposing the new epithelium which has grown beneath it.

For the first-aid treatment of all burns and scalds a plea is made for the use of dressings soaked in a 5 per cent. solution of tannic acid in water (grs. 20 of the powder to an ounce of warm water).

Vigorous cleaning and scrubbing are avoided, as we find these do more harm than good.

The tannic acid solution is applied with a soft camel-hair brush (¾ in. wide) instead of a spray.

Softening of an ordinary tannic acid crust, when covered up, is usually thought to be due to diminished evaporation from its surface. This series of cases rather suggests that evaporation plays but little part, and that the softening is nearly always due to sepsis following mechanical damage, from the rubbing of a dressing. The effect of reinforcement is entirely mechanical. The strengthening is most essential at the edge of the crust where it is in contact with skin and its organisms; here it is that separation first occurs from the friction of dressings and organisms first gain a hold. The agents used for reinforcing the crust all help to prevent this separation at the edge, and it is to this, we believe, the beneficial effect of reinforcement is due.

Our thanks are due to Prof. G. E. Gask and Sir Charles Gordon-Watson for permission to publish these cases, and to the sisters and nurses in the surgery of St. Bartholomew's Hospital for their help.

THE ÆTIOLOGY OF BREAST CANCER

By C. C. Twort, M.D. Aberd.
PATHOLOGIST TO THE MANCHESTER COMMITTEE ON CANCER
AND
A. C. Bottomley, Ph.D. Manch.
CHEMIST TO THE COMMITTEE

Among the most lowly carcinogenic agents for the epithelium of mice that we have utilised are oleic acid and some of the almost completely saturated mineral oils. It is the action of these substances, and especially the former, that we wish to discuss here. Their carcinogenic potency is such that they affect relatively little the surface and follicular epithelium, rarely inducing more than a hyperplasia; and they never excite the surface epithelium to do more than form a benign tumour, so far as our experience goes. Their action is, however, not always so benign on the sebaceous cells, and we have specimens of malignant sebaceous adenomas of mice induced as a result of their continuous applications.

A commonly observed morphological change in the skin of animals painted with carcinogenic agents is related to the sebaceous cells, and it did not escape the notice of the pioneers working with tars that sebaceous cell atrophy almost always followed their use. The most potent carcinogenic agents do not necessarily induce the greatest degree or the most rapid sebaceous cell atrophy. Most agents being a mixture of variable chemical constituents embodying both carcinogenic and non-carcinogenic compounds, some of the latter may act detrimentally on the sebaceous cells as well as the former. Among the various agents which we have utilised we have found that they have a decreasing toxic influence in the following order, the toxic gradually being replaced by a stimulating influence.

SOME CARCINOGENIC AGENTS

1. Ordinary *coal-gas tars* are the most toxic substances we have tested for the sebaceous cells, and continual application of them invariably leads to complete atrophy of the sebaceous glands in a relatively short space of time.

A few applications given over a short interval or an occasional application from time to time may, however, induce a sebaceous cell hyperplasia. Similarly an extremely dilute gas tar may either have no influence on them or may induce a hyperplasia, and even a tumour. Thus the substances which are influencing the sebaceous cells have apparently a mode of action similar to those influencing the cells of the surface epithelium. When concentrated there is destruction, somewhat weaker there is formation of malignant tumours, still weaker we have benign tumours only, and if we continue to dilute our agent hyperplasia only results, and eventually, when using an extremely dilute agent, one can detect no change at all in the sebaceous cells, which appear normal in all respects.

2. The very much more highly carcinogenic *synthetic tars* are far less toxic to the sebaceous cells than are coal-gas tars.

Often their detrimental effect upon the sebaceous cells is by no means obvious. It is probable that in coal-gas tars there are substances which are poisonous for the delicate sebaceous cells but without palpable influence on the more sturdy cells of the surface epithelium, and that the true carcinogenic compounds in both types of tar act similarly on sebaceous and surface epithelial cells of the skin. While the mechanism of the action may be similar it is evident that the degree of action is not the same; a concentration of carcinogenic compounds which may excite malignant new growths of the surface epithelium will probably cause a certain amount of sebaceous cell atrophy, while a concentration sufficient to lead to a malignant sebaceous cell tumour we should expect to leave the surface and follicular epithelial cells more or less unaffected.

3. *Shale oils* are apparently the most carcinogenic of all mineral oils, and in the carrying out of an ordinary experiment with this category of agent one usually observes a considerable amount of sebaceous cell atrophy.

To a less degree atrophy is also observed when utilising potent mineral oils obtained from petroleum oil wells, but with weakly potent mineral oils the sebaceous cells may be little affected.

4. When we come to the almost completely *saturated mineral oils*, sebaceous cell hyperplasia begins to be observed, and eventually with certain specimens of oil we may come across sebaceous adenomas.

Thus the mineral oils which are most likely to induce sebaceous adenomas are those which are highly purified with sulphuric acid, &c., such as are met with commercially, as medicinal liquid paraffins, hair brilliantines, and transformer oils. As might be expected, of two samples of mineral oil of an approximately equal degree of saturation the heavier the grade the more likely are sebaceous tumours to be induced. engine and cylinder grades being as a rule less active carcinogenically than their spindle grade counterpart.

5. The most effective sebaceous cell stimulant we have met with is *oleic acid*.

This acid causes simultaneously a sebaceous cell hyperplasia and a hyperplasia of the surface and follicular epithelium. Long-continued application may eventually lead to sebaceous adenomas and benign papillomas of the epidermis, the latter being by far the commoner. We have not meanwhile succeeded in inducing any malignant tumours with the acid used alone, presumably owing to our animals not having been subjected to applications of the agent for long enough time. We were naturally not slow to appreciate the importance of these observations with oleic acid, and their possible significance in relation to breast and other forms of cancer.

COMBINATION OF AGENTS

In several of our previous publications we have discussed the carcinogenicity of chrysene, an unsaturated aromatic hydrocarbon isolated from our synthetic tars. This substance has a relatively low degree of carcinogenicity compared with dibenzanthracene, a related hydrocarbon recently synthetically prepared by E. L. Kennaway and J. W. Cook. Chrysene is an extremely insoluble substance. Applied as a paste in medicinal liquid paraffin it may induce a few benign tumours of the surface epithelium, and occasionally one of them may become malignant, and it is noticeable that such a paste tends to have a greater stimulating effect on the sebaceous cells than has liquid paraffin when used alone. On the other hand, a paste of chrysene and oleic acid may induce many benign tumours of the surface epithelium, and it is usual for more than half of these to become malignant, provided the animal survive for a reasonable period of time. The benign tumours are somewhat late in arriving, but the malignant lag is on the whole unusually short. The effect of such a paste on the sebaceous cells is irregular, but, broadly speaking, it may be expected that in the region of the skin of animals bearing tumours of the surface epithelium there will not be much evidence of sebaceous cell hyperplasia, or there may even be some atrophy, while in the remaining animals sebaceous cell hyperplasia is the rule, and sebaceous adenomas are not exceptional. While oleic acid seems materially to increase the carcinogenic potency of chrysene and other weak agents it does not act in the same direction when mixed with strong agents such as a synthetic tar, our findings in some of our experiments being shown below. (P.=carcinogenic potency and R.P.= relative carcinogenic potency.*)

Agent.	P.	R.P.
Chrysene 7·5 % in liquid paraffin	4	100
„ 7·5 % „ oleic acid	23	575
Gas tar	133	100
„ „ and 10 % oleic acid	96	72
Synthetic tar B/3 10 % in oleic acid ..	206	122
„ „ „ 10 % „ liquid P. ..	169	100
„ „ B/10 10 % „ „ „ ..	721	100
„ „ „ 10 % „ oleic acid ..	580	80
Shale oil S, 10 % in liquid paraffin	0	—
„ „ 10 % „ oleic acid	0·4	Inf.
„ „ 20 % „ liquid paraffin	0	—
„ „ 80 % „ oleic acid	16	19
„ „ pure..	85	100
Californian oil 9, pure	2	100
„ „ 80 % in oleic acid ..	5	250

Inf.= infinite.

There may, however, be a vast difference in the action of a second substance when it is mixed with the first agent before applying and when it is applied separately. This is illustrated in the following experimental results.

Experimental conditions.	P.	R.P.
Tar B/1 on skin previously sensitised with { oleic acid ..	1105	118
Tar B/1 on skin previously sensitised with { lactic „ ..	650	69
Tar B/1 control	940	100
Tar B/19 on skin previously sensitised with oleic acid	1619	121
Tar B/19 control	1339	100
Shale oil, skin treated at intervals with lanolin	0	0
Shale oil control..	85	100
„ „ treated in afternoon with lanolin	19	7
„ „ mixed with 10 % lanolin	21	7
„ „ control..	293	100
Gas tar 1 % mixed with 0·1 % lanolin (9 to 1)	143	128
Gas tar 1 % treated with lanolin in afternoon.. .. .. Below	10	9
Gas tar 1 % control	112	100

It is to be noted that previous applications of oleic acid sensitise, while previous applications of lactic acid desensitise. The carcinogenic activity of shale oil is lessened by the admixture of or separate application of lanolin. In the case of gas tar, admixture of the lanolin sometimes increases its activity while separate application lessens it. Also, if oleic acid is applied to one area of skin and tar subsequently applied to another, the activity of the tar is decreased. The reasons for these differences are quite explicable but they cannot be entered into here.

THE TUMOURS AND THEIR BIOLOGICAL SIGNIFICANCE

The accompanying microphotographs will serve to illustrate the type of tumours we have encountered.

Figs. 1 and 2 show a typical malignant sebaceous-celled tumour induced by the application of shale oil treated with an equal volume of pure sulphuric acid. The oil was registered as non-carcinogenic, and the particular tumour under discussion was the sole representative among the 100 animals utilised. The tumour formed a huge mass in the neighbourhood of the left shoulder and axilla, with an absence of obvious metastases.

Figs. 3 and 4 illustrate a massive malignant tumour situated beneath a squamous-celled epithelioma in an animal painted with a chrysene-oleic acid paste. The tumour is essentially basal-celled in nature with what we call *sebaceous cell inclusions*; an intermixed intermediate type of tumour occasionally met with when utilising certain agents. Such agents will in some animals induce ordinary squamous epitheliomas, often with a basal-celled tendency, or benign sebaceous-celled tumours, and sometimes the intermixed type of tumour referred *to*.

Fig. 5 shows a pure basal-celled growth from the same group of animals.

Figs. 6 and 7 show another of these intermixed tumours in the early stage before the sebaceous cells have disintegrated to form the cyst-like spaces seen in Fig. 3.

Photomicrographs of other varieties of experimental tumours, including benign sebaceous adenomas induced by our agents, have been previously published.[1]

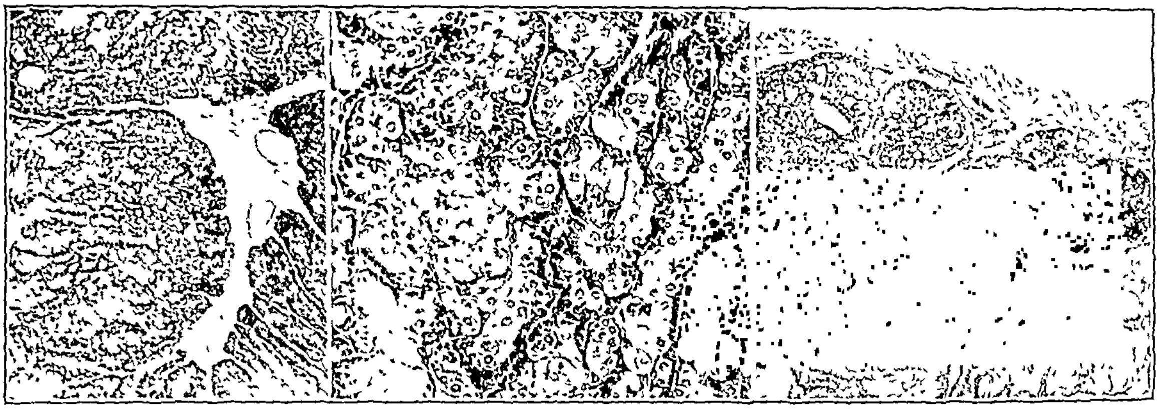
FIGS. 1 2 3



Malignant sebaceous tumour. (× 82.) Malignant sebaceous tumour. (×165.) Cystic basal epithelioma. (× 19.)

In order to evaluate these observations we must consider for a moment the biological significance of the particular agents we have been utilising. Oleic acid is of course a constituent of practically all fats originating from animals and plants, and it is important to bear in mind that it is an unsaturated fatty acid *not very distantly related chemically to the olefins.* Consequently we shall expect this acid to be present at some time or other during the decomposition of fatty organic tissues, and it requires no elasticity of the imagination to visualise its possible importance as regards the genesis of many cancers. If oleic acid is capable of inducing tumour-formation of the sebaceous cells and of the surface epithelial cells of the skin, we see no logical reason why it should not act similarly on other epithelial tissues. We cannot however, in our opinion, argue along the same lines as regards our mineral oils and tars. In so far as we are here dealing with agents which are soluble in fats and most ordinary organic solvents, it is not surprising that they are able to penetrate the skin and thereby influence the basal cells, &c. On the contrary, because they are insoluble in water we should not expect them to influence mucous membranes which are mostly bathed in mucus, for we expect the mucus effectively to prevent even surface contact of a mineral oil with the living cells. Although we have examined many thousands of animals, among which some 12,000 have been bearing skin tumours, we have in no single instance met with a tumour of the *mucous membranes.* It is of some significance that we have no record of tumours of tongue or palate when one remembers that it is the habit of mice to clean the back with the paw and to remove the agent from the latter with the tongue. On the other hand, it must also be remembered that we have no record of an internal tumour following treatment with oleic acid, but of course when the animals ingest the acid we are in the presence of a natural substance in a natural situation (in food), and it is presumably dealt with by the digestive juices of the alimentary tract in the ordinary way. We must mention a tumour of the stomach which has recently come to hand, although we have little doubt that it is a rare form of spontaneous tumour.

The tumour was a large squamous-celled epithelioma of the forestomach of a mouse which had been painted for 20 weeks with a watery solution of a mixture of chrysene ammonium and sodium sulphonate, and subsequently injected subcutaneously four months previous to death with a synthetic tar sodium and ammonium sulphonate. The tumour appeared to have its origin at the junction of the fore and glandular part of the stomach, and was invading the liver and adjacent organs.

CANCER OF THE BREAST

The possible part which may be played by oleic acid in the genesis of cancer of the breast has been the main reason why we have studied closely the action of the acid on the skin, and especially on the sebaceous cells. Sebaceous *cells* and *breast cells* are modified epidermal cells, and from the biological point of view the secreting cells of the breast are nothing more than sebaceous cells which have differentiated along another line in order to perform a special function. We have not meanwhile attempted to induce cancer of the breast by the application of oleic acid, for although successful tumour induction would be of interest we feel that negative results would be of little value, because we could not perform an experiment under the conditions occurring naturally. It is not easy to surmise the actual *quantity of acid which would be necessary for the* induction of a breast carcinoma; it would probably be smaller than that required to induce sebaceous tumours, and very much smaller than the quantity necessary to induce malignant tumours of the surface epithelium.

It has been conclusively shown statistically that the female breast which is not allowed to function normally is more liable to develop cancer than one to which a child has suckled over a definite period of time, and then allowed a lengthy period of rest until a subsequent child is born. Anything contrary to nature such as no lactation, under-lactation, and over-lactation, or some other extraneous factor interfering with the natural course of events may predispose to cancer, and in view of our present knowledge it is not difficult to understand why. We can only discuss under-lactation here.

In the event of no lactation or under-lactation we shall have decomposition of the excretory products and consequent liberation of free oleic and other fatty acids. The products of decomposition will be unable to find their way to the surface and will lie in situ in the gland acini and ducts until removed by the body fluids and wandering cells of the host. If, as we surmise, the oleic acid and probably also related fatty acids act carcinogenically on the secreting cells of the breast we must not lose sight of the fact that they may be operating in particularly favourable surroundings. Milk is necessarily a carrier of abundant growth stimulins and it is certainly not deficient in vitamins, so that we are bound to assume an extremely favourable environment for the acid to exert its malignant influence. Applications of lactic and butyric acid to the skin have resulted in no obvious hyperplasia of the surface epithelium, in fact we have found it somewhat atrophied in many animals treated with these acids. In our experiments there was also no apparent effect on the sebaceous cells.

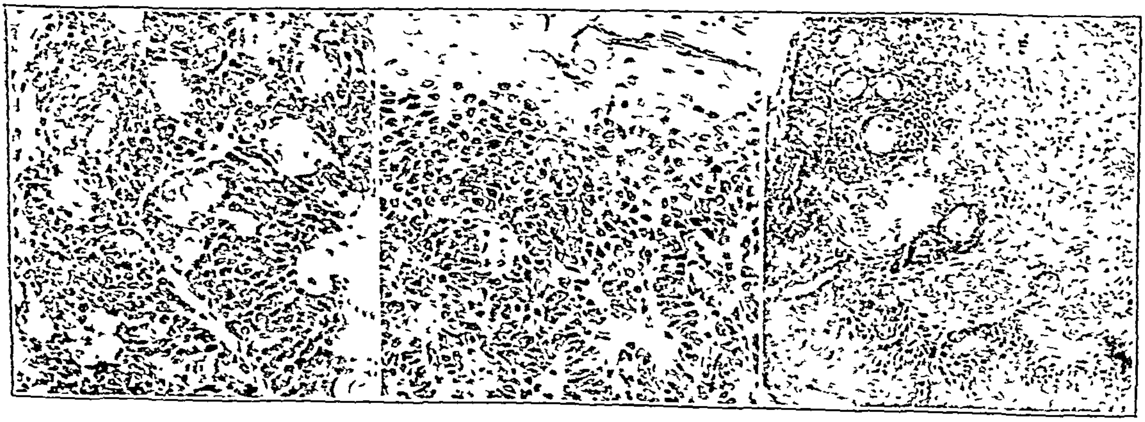
CHEMICAL ASPECTS

On attempting to correlate carcinogenicity with chemical constitution one soon has to admit that some of the carcinogenic agents have very little in common.

In the case of mineral oils we find that potency runs roughly parallel with unsaturation, but the nature of the unsaturated constituents is unknown. Chrysene and 1·2 : 5 6 dibenzanthracene are aromatic hydrocarbons consisting of conjugated benzene rings, and give direct evidence of their unsaturated character only in a few reactions. Oleic acid is unsaturated in the strict sense of the word, having a true double bond in the middle of a straight carbon chain, which also carries a terminal carboxyl group.

So far the only common factors appear to be a fairly large number of carbon atoms directly united to one another, and a certain degree of unsaturation, ethylenic or aromatic. Such a description includes too great a variety of compounds to be of much value, and any attempt to narrow it down appears to exclude substances which have a definite, if slight, carcinogenic action. This variety is rather bewildering in view of the specificity of so many biological reactions —e.g., the different physiological effects of *d* and *l* forms of so many substances, the activity of vitamin D compared with ergosterol, or the importance of the length of chain in determining the effectiveness of chaulmoogric acid and its homologues against *B. lepræ*. On the other hand there are many different types of hypnotics and local anæsthetics.

FIGS. 4 5 6



Cystic basal epithelioma. Sebaceous cell inclusions. (×165.)

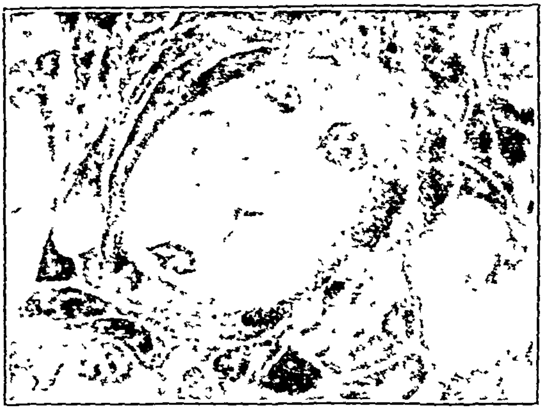
Early basal malignancy. (×165.)

Small basal cell tumours. Sebaceous cell inclusions. (× 82.)

Further difficulties arise in connexion with the combination of agents. Thus we have the following results :—

1. Oleic acid alone gives rise to a few benign tumours.
2. Chrysene in oleic acid, after long application, produces tumours of the surface epithelium which become malignant in a relatively short time.
3. Chrysene in liquid paraffin is much less potent than in oleic acid.
4. The synthetic tars B/10 and B/19, applied in liquid paraffin or chloroform, are very potent.
5. Addition of oleic acid to these tars reduces or at any rate does not increase their potency.

FIG. 7



Sebaceous cell inclusions. (× 1000.)

6. A 0 15 per cent. solution of tar B/19 in oleic acid has a potency not far removed from a similar solution of chrysene.

Perhaps the simplest hypothesis is that two factors (or two types of factors) are involved. These may be tentatively described as (*a*) a sensitising factor and (*b*) a stimulating factor which promotes cancerous development of the sensitised cells. One or both of these factors may be present within the organism as a result of pathological conditions, or perhaps normally to a slight extent. On this view the above results can be interpreted as follows :—

1. Oleic acid is a rather weak "sensitiser."

2 and 3. Chrysene is a fairly powerful stimulant.

4. The synthetic tars, which are complex mixtures, contain both factors.

5 and 6. Oleic acid is a weaker "stimulant" than those present in the tar and acts as a diluent for them.

To obtain direct evidence for the assumption made in Case 4 it would be necessary to resolve a tar into two fractions whose relation to one another would be analogous to that of chrysene and oleic acid. This has not been satisfactorily achieved, but one experiment gave a hint of the possibility.

A fraction was separated from tar B/19 by condensation with ethyl oxalate and subsequent regeneration of the hydrocarbons. This fraction was only slightly toxic. The residue was nearly as potent as the original, but there was a curious lag before any tumours appeared, compared with the re-mixed extract and residue.

In the case of the mineral oils it has sometimes been found that the residues after extraction with methyl sulphite or alcohol produce fewer tumours than the original, but about the same number become malignant. This suggests the preferential removal of a sensitising factor, since only the initial processes are impeded.

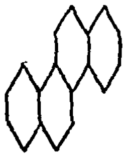
The available data do not permit of any useful attempt to correlate sensitising action with chemical constitution. We may hazard a guess that unsaturation is an important factor, but it is impossible at present to say whether the action is chemical or physical. In the case of the "stimulating" factor, however, recent developments in other fields have opened up interesting possibilities.

GROWTH-STIMULANTS

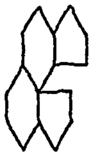
Since active proliferation is a characteristic of cancer cells we have long suspected some relationship between carcinogenic agents and normal growth-stimulants. We therefore regard the chemistry of vitamins and the hormones of pregnancy, &c., as being relevant to our problem.

From a chemical standpoint the best known vitamins are the fat-soluble A and D. Of these, vitamin A appears to be closely related to the terpenes, and probably consists largely of a long, branched carbon chain. We know no carcinogenic substance of this type though analogous substances may be present in the oils. Vitamin D is a member of the sterol group being formed by the isomerisation of ergosterol under the influence of suitable irradiation.

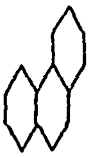
The fact that dehydrogenation of sterols under vigorous conditions produces chrysene I.[2] was suggestive, but it was generally believed that the sterol nucleus was represented by II. and that the formation of chrysene involved a profound rearrangement.



I



II



III

Diels obtained other products under milder conditions and attributed to these formulæ of the fluorene and indene types. In view of this, coupled with Kennaway's observation that cholesterol gives a carcinogenic tar on heating, admittedly to a high temperature, we suspected that hydrocarbons of these types might be the active agents in our tars. The condensation with ethyl oxalate, referred to above, was designed to test this hypothesis, but the extract was relatively inactive.

Recently however, the older view of the structure of sterols has met with much criticism, and the most recent suggestion is that the carbon skeleton of chrysene is present in the original sterol. Bernal[3] has produced evidence for this from X ray and optical measurements, while Rosenheim and King[4] have advocated it on chemical grounds.

From the urine of pregnancy three characteristic substances have been isolated by various workers—viz., pregnandiol, ketohydroxyœstrin, and trihydroxyœstrin. Of these, pregnandiol has no marked physiological action, but ketohydroxyœstrin produces œstrus in immature or ovariectomised animals and the same result is obtained to a smaller degree with trihydroxyœstrin. The œstrin derivatives are formed in the ovary in response to stimulation by the anterior pituitary hormones, and it is believed that they control the earlier stages of the œstrous cycle, inducing the pro-œstrus growth of the uterine tissues and, in some species, a characteristic modification of the epithelial cells of the vagina. These substances are found at all times in normal female blood, but the amount varies during the œstrous or menstrual cycle and increases greatly during pregnancy.

The structure of the œstrin derivatives has been studied by several workers, employing chemical methods, X ray and optical measurements,[5] and the properties of monomolecular films.[6] The results all favour a nucleus of the phenanthrene type III. It will be observed that chrysene contains this nucleus. Pregnandiol is a sterol.[7] It is crystallographically related to ergosterol on the one hand and to the œstrin derivatives on the other (Bernal). It may prove to be an intermediate stage in the formation of physiologically active substances.

The hypothesis that chrysene is the basis of the sterol nucleus has not been generally adopted, so it would be unwise to base too many speculations on it, but from our point of view it is very attractive and we await further developments with great interest. Kennaway and Cook[8] have recently suggested that cancer-producing substances may arise in the body by abnormal sterol metabolism. We have been led into similar speculations from a rather different viewpoint. If the latest formulæ prove to be correct it will mean that vitamin D, œstrin and the carcinogenic substances chrysene, and the 1·2 benzanthracene derivatives all contain the carbon skeleton of phenanthrene. To what extent this may determine their growth-promoting properties remains an open question.

The point we wish to emphasise is the possible significance of the association of growth-stimulins, or substances capable of transformation into growth-stimulins, with oleic acid, with special reference to breast cancer. It is perhaps significant that the cholesterol content of the blood increases greatly during pregnancy, diminishing towards the end and during lactation. This hypercholesterinæmia passes off more quickly in mothers who suckle their children than in those who do not, owing to the secretion of cholesterol in the milk. It is also of interest to note that there are disturbances of the fat metabolism during pregnancy, and that the fœtal liver stores up fat which is less saturated than connective tissue fat. We are not prepared to be dogmatic about the relevance of these observations. We do feel, however, that facts of this nature should be taken into account, and that only by combining observations taken from a number of different fields, along some such lines as we have suggested in this paper, shall we reach a solution to problems connected with our own researches.

Our interest was recently aroused by seeing a report of a paper by Taylor[9] in which it was stated that petroleum oil or mineral oil prevented the reproduction of animals even when wheat-germ oil was included in the diet. Unfortunately we have only been able to obtain abstracts of this paper, but so far as we can judge from these, the author's results are somewhat contrary to our own observations.

SUMMARY

It is suggested that the chief ætiological factor concerned in carcinoma of the breast is a group of compounds containing the carbon skeleton of phenanthrene acting in conjunction with oleic or other unsaturated fatty acids.

The photographs are by R. Combes.

THE TREATMENT OF PERNICIOUS ANÆMIA BY MARMITE

BY ALEXANDER GOODALL, M.D., F.R.C.P. EDIN.

PHYSICIAN IN ORDINARY TO THE ROYAL INFIRMARY OF EDINBURGH

THE publication by Lucy Wills[1] of a series of cases of "pernicious anæmia" of pregnancy and "tropical anæmia" successfully treated by marmite raises many questions of importance. It is unnecessary for our present purpose to discuss the identity of her cases with ordinary pernicious anæmia. There is no question about their close similarity, and her results suggested the possibility of using marmite as an alternative or supplement to liver or liver extracts in ordinary pernicious anæmia. Stanley Davidson[2] has already published the results in three cases. One case did well and two did not. Davidson suggests that tropical and non-tropical macrocytic anæmia are different conditions, that the anti-anæmic factor in liver and vitamin B are not related, and that any benefit following the use of vitamin B is due merely to improving the efficiency of the gastro-intestinal tract.

MAINTENANCE CASES

Since the publication of Wills's paper I have treated all my "maintenance" cases with marmite. Without exception these have done well. I show the results of eight such cases, treated by marmite only, for periods of from seven to twelve months. I have equally satisfactory results in a further series of six cases treated by marmite for periods under six months. Other cases are referred to which bring the total up to 19.

Table of Cases of Old-standing Pernicious Anæmia treated (after recovery) with Marmite only for not less than seven months.

Case.	Sex.	Age.	Date of admission.	R.B.C.	Hb.	Date marmite started.	R.B.C.	Hb.	Date last observed.	R.B.C.	Hb.

R.B.C.—Red cells in millions per c.mm.
Hb.—Hæmoglobin as percentage of normal.

The Table summarises the eight maintenance cases treated with marmite. Several were originally cases of great severity, and most of them have already been published[3] in greater detail. The date of admission to my ward is not to be taken as any guide to the previous duration of illness. Case D had been transfused on two occasions. The maintenance dose of marmite has never exceeded ʒi thrice daily. In a few cases it is only ʒi twice a day.

PRIMARY CASES

The following are notes of primary cases treated with marmite only.

CASE 1.—Female, married, aged 37, admitted Nov. 18th, 1931; stated she had not felt fit since a puerperal hæmorrhage ten years before. Lately had severe breathlessness, palpitation, and weakness. Blood showed 1·7 million corpuscles per c.mm.; average size increased; Hb., 40 per cent.; leucocytes, 5000. Van den Bergh direct positive (weak, delayed). Icteric index, 9. Wassermann negative. Achlorhydria. Some tingling of feet and impairment of cutaneous sensibility. Marmite was administered in half-ounce doses thrice daily. A reticulocyte response of 20 per cent. occurred on the eighth day, and increased to 25 per cent. on the tenth day, and remained above 10 per cent. for eight days. On Dec. 15th she had 50 per cent. of hæmoglobin, and owing to domestic trouble went home. On April 26th, 1932, she had 2·5 million corpuscles, with 60 per cent. of hæmoglobin. Her doctor states she is now in good health.

CASE 2.—Male, aged 53, admitted June 6th, 1932. Suffered from weakness and dyspepsia for a year, increased weakness and giddiness for three weeks. Red corpuscles, 2·1; Hb., 52; leucocytes, 6000; films typical. Van den Bergh positive delayed direct. Icteric index, 12. Wassermann negative. Achlorhydria. No nerve symptoms. Marmite, a tablespoonful thrice daily, was started next day. Reticulocytes were 6·5 per cent. two days later, and 9 per cent. on the fourth day. Progress was uneventful but the blood progress showed the very unusual feature of an increase of hæmoglobin more rapid than the increase of corpuscles. Patient was discharged on July 19th with 3·5 million red corpuscles and 95 Hb. The marmite dosage was reduced to ʒi t.i.d. On August 3rd he reported, feeling fit, with 4·5 red cells and 98 Hb.

CASE OF RELAPSE

The following was a relapse case treated with marmite only.

CASE 3.—Male, aged 59, admitted March 17th, 1932. Two years previously became easily tired, suffered from giddiness, tinnitus, tingling in the limbs, and assumed a yellow colour. In December, 1930, he collapsed in an Aberdeen post office, and was conveyed to the Royal Infirmary, where he was under the charge of Prof. Stanley Davidson. He was treated with Ventriculin and, later, with liver extract. About five months ago he became careless about taking liver, and symptoms returned.

On admission he showed a yellowish pallor; red corpuscles numbered 1·3; Hb., 31 per cent.; leucocytes, 4600; reticulocytes, 1 per cent. Spleen was slightly enlarged. Pyorrhœa. Achlorhydria. Positive van den Bergh. Icteric index, 20. Tingling of legs. Sluggish knee-jerks. Some impaired sensibility. On March 19th, 1932, the teeth were extracted and a sharp hæmorrhage followed. Red cells fell to 1·05 and Hb. to 25. Marmite ℥ss t.i.d. was begun on the 21st. By the 28th reticulocytes had reached 11 per cent.; red corpuscles were 1·3 and Hb. 27. A month later red cells were 3·2 and Hb. 67. Two months later red cells were 3·9; Hb. 81. The marmite dose was reduced to a teaspoonful thrice daily. On July 20th the red cells were 3·7, and Hb. 80. On August 17th the red cells were 4·0, and Hb. 80.

LIVER EXTRACT FOLLOWED BY MARMITE

The following cases were treated with marmite after a preliminary course of intravenous liver extract.

CASE 4

Date in 1932.		Blood examination.			Treatment.
		R.B.C.	Hb.	Reticulocytes per cent.	
April	22nd	1·6	34	0·6	Pernæmon* 5 c.cm. daily.

July	29th	5·3	98	—	" ℥ i bis in die.

*Liver extract (Crookes) for intravenous use.

CASE 4.—Male aged 50. Complained of weakness and breathlessness for four years. Sore tongue. Prickling sensation in limbs. Patient had a yellowish colour. Spleen was just palpable. Achlorhydria. Reflexes normal. Wassermann negative.

CASE 5.—Male aged 61. Complained of breathlessness and dyspepsia. Showed a pale yellow colour. Spleen not enlarged. Achlorhydria. No nerve symptoms. Wassermann negative.

CASE 5

Date in 1932.	Blood examination.			Treatment.
	R.B.C.	Hb.	Reticulocytes per cent.	
May 7th	2·3	42	0·5	Pernæmon 5 c.cm. intravenously daily.
" 16th	2·8	62	3·3	Marmite ℥ ss t.i.d.
June 3rd	4·8	95	—	" ʒ 1 "

These cases seem to prove that marmite is efficacious in the treatment of the average case of pernicious anæmia. The dosage employed has been a tablespoonful thrice daily while the patient is ill, and a teaspoonful twice or thrice daily to maintain health. Although marmite has been found to cause nausea and vomiting, we have only once encountered difficulty in getting a patient to take it, and it was as difficult to get her to take liver or liver extract. The marmite may be dissolved in warm water like a meat extract, may be spread on bread and butter, or may be stirred into milk. Most patients find it palatable and welcome it as a change from liver. It is a pleasant solution to the difficulty that patients in remote districts often find in obtaining liver, and in getting liver in good condition in warm weather. Moreover, marmite would appear to be a useful alternative to liver in gouty, rheumatic, and high pressure subjects.

EFFICACY OF MARMITE AS COMPARED WITH OTHER SUBSTANCES

In this connexion all that can be discussed is the efficacy of different remedies in the dosage usually employed.

I maintain[3] that transfusion of a pint or thereby of compatible human blood is the most powerful stimulus to hæmatogenesis that can be employed, and the transfused corpuscles may save life in emergency. Nearly as efficacious as transfusion (save for the supply of hæmoglobin) is intravenous injection of an active preparation of liver in the recommended dosage. It is an advantage to start off acute cases with intravenous injection because of the great rapidity of action and the consequent saving in hospital beds.

There is, I think, little to choose between the effects of whole liver, liver extract, stomach, stomach extracts, and marmite given by the mouth. One point of difference in the case of marmite emerges in the primary and relapse cases, and that is the persistence of a high colour-index. On liver treatment corpuscles are regenerated more quickly than hæmoglobin, so that the colour-index falls. On marmite the hæmoglobin content outstrips the increase of corpuscles, and the blood picture tends to remain macrocytic even when the hæmoglobin may be so high as 60 per cent. This feature may be regarded as unfavourable to marmite, but the end-result is just as good as that effected by liver.

A point of practical importance is that no extract seems to be so efficacious in the cord degeneration of pernicious anæmia as whole liver.

The question of the vitamin content of commercial liver and stomach preparations, and the rôle of these vitamins in hæmatogenesis has been much discussed (Gilroy[4] and others). It is of interest that an anti-anæmic factor of purely vegetable origin now falls to be investigated.

SUMMARY

Observations on 19 cases of pernicious anæmia indicate: (1) That the administration of marmite in small doses is an adequate means of maintaining cases of recovered pernicious anæmia in good health. (2) Marmite in large doses is a satisfactory remedy for primary and relapse cases of pernicious anæmia of moderate severity. (3) Time may be saved in moderately severe cases by a preliminary course of intravenous injections of liver extract given daily for five or seven days. (4) In very severe cases intravenous injection of liver extract is necessary, and in the most severe cases transfusion of blood is imperative.

A CONSERVATIVE TREATMENT OF ECLAMPSIA

REPORT OF ONE HUNDRED CASES *

BY E. A. GERRARD, M.B. MANCH., M.C.O.G.
REGISTRAR, ST. MARY'S HOSPITALS, MANCHESTER
AND
R. L. NEWTON, M.B. MANCH., M.C.O.G.
RESIDENT SURGICAL OFFICER, ST. MARY'S HOSPITAL, HIGH-STREET, MANCHESTER

THE cases on which this paper is based comprise the patients suffering from eclampsia who were admitted to St. Mary's Hospital, Whitworth-street, Manchester, during the three and a half years before February, 1932. In this period the post of resident obstetric surgeon was held consecutively by us, and we are indebted to the honorary staff for permission to present this report.

We propose to review briefly the treatment of eclampsia at the hospital during the 20 years previous to the adoption of the present method, to explain the reasons for the change made in 1928, and to compare results; for true comparative data regarding treatment in this disease can be obtained only by studying the results of different methods carried out in one district, preferably in one institution. It is only necessary to compare the types of case described as severe in various different countries, to realise that what may be considered severe in one place is looked upon as mild in another.

The cases admitted during the years 1908 to 1928 fall, as regards treatment, into two very definite groups. No routine method was in vogue before 1920, but the main features were purgation and diaphoresis, with occasional resort to Cæsarean section and accouchement forcée. Early in 1920, however, the Dublin method was adopted at St. Mary's Hospital, and Table I. shows that the maternal mortality fell from 35·6 per cent. to 19·8 per cent.

During the first eight months of 1928, however, 28 cases were treated with 8 deaths, a mortality of 29·6 per cent. It was felt, therefore, that the results of the Dublin method in our hands were not all that could be desired, the chief objection being that the repetition of colon lavages advised in a severe case appeared to produce a considerable degree of shock. The culminating point was reached when in one case one of us was standing during a lavage with a finger on the patient's pulse and found that it suddenly disappeared; although restoratives were immediately applied, the heart could not be made to beat again.

---

Outline of the Treatment

Other methods were considered, and naturally we were much impressed by the results obtained by Stroganoff. On theoretical grounds, however, we were not inclined to follow his technique absolutely. Our criticism was, that as a routine treatment of a pregnancy toxæmia is and always has been by elimination, it seemed irrational to discard eliminative measures entirely on the appearance of a fit, and thereafter to proceed on purely sedative lines. We decided, therefore, to try to combine the two methods, and in view of the fact that heart failure is the cause of death in many cases, a routine four-hourly heart stimulant seemed desirable. The method of procedure was as follows:—

Hours. TREATMENT A

0. Morphine sulph. gr. ¼, coramine 1 c.cm.
½. Gastric lavage, leaving in stomach castor oil 2 oz. and croton oil 2 minims. Colon lavage, leaving in mag. sulph. 2 oz. (anæsthesia if required).
1½. Chloral hydrate grs. 30 per rectum or mouth.
3. Morphine sulph. gr. ¼.
4. Coramine 1 c.cm.
7. Chloral hydrate grs. 30.
8. Coramine 1 c.cm.
12. Coramine 1 c.cm., chloral hydrate grs. 20.
16. Coramine 1 c.cm.
20. Coramine 1 c.cm., chloral hydrate grs. 20, and later chloral hydrate grs. 20, 8-hourly, if required.

Coramine is a Ciba preparation of camphor and has proved quite satisfactory. The patient was treated in a darkened labour ward and precautions taken to ensure absolute quietude. Strict attention was paid to keeping the patient's air passages clear, and oxygen was resorted to in the presence of cyanosis.

The results obtained in the first few cases were distinctly encouraging, and the method was deemed worthy of an extended trial. Late in 1929, however, by which time some 40 cases had been treated, we read a paper by O. H. Schwarz and W. J. Dieckmann,[1] advocating the use of intravenous glucose and intramuscular magnesium sulphate as follows:—

(1) Magnesium sulphate, 10 c.cm. of 25 per cent. solution intramuscularly on admission, and 5 c.cm. after each convulsion.

(2) Colon and gastric lavage leaving 60 c.cm. of saturated solution of magnesium sulphate in stomach.

(3) Glucose 1000 c.cm. of 20 per cent. solution intravenously, two, three, or four times daily, depending on the case.

It was suggested that this might form a useful addition to our routine which now became:

Hours. TREATMENT B

0. Morphine sulph. gr. ¼, coramine 1 c.cm.
   Magnesium sulphate 10 c.cm. of 25 per cent. solution intramuscularly, and 5 c.cm. after each convulsion.
   Dextrose 1000 c.cm. of 20 per cent. solution intravenously repeated if necessary.
½. Gastric lavage, leaving in stomach castor oil 2 oz. and croton oil 2 minims. Colon lavage, leaving in colon mag. sulph. 2 oz. (anæsthesia if required).
1½. Chloral hydrate grs. 30 per rectum or mouth.
3. Morphine sulph. gr. ¼.
4. Coramine 1 c.cm.
7. Chloral hydrate grs. 30.
8. Coramine 1 c.cm.
12. Coramine 1 c.cm., chloral hydrate grs. 20.
16. Coramine 1 c.cm.
20. Coramine 1 c.cm., chloral hydrate grs. 20, and later chloral hydrate grs. 20, 8-hourly, if required.

Apart from this modification the whole series of 100 cases have been treated on identical lines. Our attitude has been entirely conservative, and in cases where the patient was in labour, the eclampsia, of itself, was not considered an indication for operative interference of any kind. When, however, a complication arose it was dealt with on ordinary lines, as in a non-eclamptic case.

No case was discharged from hospital undelivered. In a few cases induction of abortion or labour was carried out on account of persistent albuminuria after recovery from the eclampsia.

The mode of delivery was as follows:—

Natural forces	54	Forceps	17
Induction followed by delivery by natural forces	7	Version and extraction.	1
Abortion	8	Breech extraction ..	1
Induced abortion ..	3	Cæsarean section ..	1
		Craniotomy	1
		Five cases died undelivered	

Comparison of Results

The results of the various methods are set out in Table II.

TABLE II

MATERNAL MORTALITY

	Total.		Deaths and per cent.
1908 to Mar., 1920 ..	430	No routine method	153 (35·6)

Treatment B— 46 cases	58·7	41·3

---

[1] Amer. Jour. Obst. and Gyn., 1929, xviii., 515.

This Table shows that the maternal mortality has fallen considerably but the fœtal mortality only slightly since adoption of the present routine.

We now propose to review certain aspects of the 100 cases.

Classification of Cases

Clinically, cases of eclampsia are often grouped under three headings: (*a*) those who will recover under any treatment; (*b*) those who will die despite the best treatment; and (*c*) an intermediate group who are amenable to good treatment. A classification of this kind can, however, hardly be considered scientific, and we propose in this paper to group the cases under two headings only—namely, severe and mild.

We have considered as severe any case where: (*a*) coma was present; or (*b*) the number of convulsions exceed six; or (*c*) the temperature rose above 103°. All other cases are grouped as mild. Using this classification we find :—

Mild: 58 cases. Average number of convulsions 2·7 per cent. Mortality nil.

Severe: 42 cases. Average number of convulsions 8·0 per cent. Mortality 7 = 16·6 per cent.

The following is a comparison of results in severe cases by treatment A and treatment B.

Treatment A.—19 cases. Average number of convulsions 8·9. Mortality 4 = 21 per cent.

Treatment B.—23 cases. Average number of convulsions 7·6. Mortality 3 = 13 per cent.

It will be seen that the mortality was definitely lower under treatment B, but that the cases were probably not quite so severe.

CONVULSIONS

The average number of convulsions in all cases was 4·3 per cent. It will be recognised, however, that the total number of fits per case must be to a certain extent influenced by the efficiency or otherwise of treatment. In relation to this, we may state that convulsions are as a rule controlled completely within a few minutes of the intravenous administration of dextrose. The average number of convulsions in fatal cases was 15·5. The highest number followed by recovery was 22. One patient had convulsions continuously for 1½ hours but recovered.

Coma was present in 36 cases, of whom 6 died. Rise of temperature to 103° was recorded in 8 cases, 2 of whom died.

Œdema was present in 79 cases, 6 of whom died. It is interesting to note that the patient who died, having neither œdema nor coma, had a temperature of 105°.

STAGE OF PREGNANCY AND PARITY

No case occurred before the 20th week, the incidence being as follows :—

20–24 weeks	3 cases	1 death
25–28 „	14 „	0 „
29–32 „	12 „	3 deaths
33–36 „	23 „	1 death
37–40 „	48 „	2 deaths

The incidence of eclampsia would seem to increase steadily during the latter months of pregnancy. The relationship to parturition was :—

Antepartum	43 cases.	Mortality 3	(6·9 per cent.)
Intrapartum	29 „	„ 3	(10·3 „ „)
Postpartum	18 „	„ 1	(5·5 „ „)

This corresponds with the usually accepted ideas both as regards frequency and mortality in the three types of case.

Of the 100 patients, 72 cases were primigravidæ, of whom 4 died; 10 cases were secundiparæ, of whom 1 died; and 18 cases were multiparæ, of whom 2 died. This agrees with most published statistics to the effect that the disease is most fatal in multiparæ.

ALBUMINURIA AND BLOOD PRESSURE

The relationship of the eclampsia to albuminuria may be shown as follows :—

On admission.—Grs. 2 or over by albuminometer, 94 cases; trace of albumin, 1 case; no albumin, 5 cases.

On discharge.—Registrable by albuminometer, 3 cases; trace of albumin, 12 cases; urine clear, 78 cases.

None of the cases without albumin died. This is contrary to the general impression that absence of albumin is a very bad sign. We hope to follow up all the cases at some future date.

The *blood pressures* showed considerable variation, the average systolic pressure being 150·5 mm. Hg. The lowest pressure recorded was 93 and the highest 230. The mean figures in severe and mild cases approximated closely, being 150·2 in severe cases and 150·7 in mild. The average pressure in cases who died was 146·6. The average blood pressure on discharge was 128·5. The suggestion offered by these observations is that the blood pressure does not serve as a reliable aid to prognosis.

Antenatal Care

During the period under review 9116 patients attended the St. Mary's Hospital antenatal clinic. Of these, 7 developed eclampsia, but all recovered under treatment. Short notes of these are as follows.

No. 35. Admitted from clinic owing to severe albuminuria, had one fit only, four hours later, following enema. Responded to treatment and did not go into labour. Induction by bougie six days later. Normal delivery. Urine clear on discharge.

No. 44. Admitted from clinic owing to severe albuminuria, went into labour after enema, was delivered, and had two fits, postpartum. Responded to treatment. Urine clear on discharge.

No. 49. Admitted from clinic owing to severe albuminuria, went into labour after an enema, was delivered, and had one fit postpartum. Responded well to treatment. Urine clear on discharge.

No. 65. Had not attended clinic for five weeks, urine clear at last visit. Postpartum eclampsia, seven fits. Good response to treatment. Urine clear on discharge.

No. 84. A "District" case. Had attended the clinic three weeks previously, when the urine was clear. Postpartum eclampsia, eight fits. Responded to treatment. Urine clear on discharge.

No. 89. A "District" case. Last visit to the clinic was eight weeks previously. The urine was then clear. Postpartum eclampsia, six fits. Good response to treatment. Urine clear on discharge.

No. 93. Admitted from clinic owing to severe albuminuria at 34 weeks. Routine treatment was carried out for two weeks without any improvement, so labour was induced. Patient had one fit postpartum, but responded satisfactorily to treatment. Urine clear on discharge.

In three cases, therefore, the patient had not attended the clinic for some time, the urine on her last visit having been clear. All developed severe postpartum eclampsia. In two cases labour followed the institution of eliminative treatment for albuminuria. Both developed mild postpartum eclampsia. In one, antepartum eclampsia resulted within a few hours only of eliminative treatment being commenced. The patient did not go into labour, but was induced later. In the other case, eclampsia followed labour, induced for persistent albuminuria.

Regular antenatal supervision would seem, therefore, to be an excellent prophylactic against eclampsia.

The Fatal Cases

The following are brief notes on the fatal cases :—

CASE 27.—Patient, aged 27, admitted at 4.45 P.M. on June 11th, 1929, seven hours after the forceps delivery of her fourth child, which was stillborn. During pregnancy there had been several attacks of antepartum hæmorrhage.

Five fits after delivery but before admission. Blood and albumin found in the urine, the B.P. was 100/75. In spite of treatment she became rapidly worse, and died 5½ hours later.

Autopsy showed no abnormal features other than definite softening of the brain substance.

CASE 32.—A case of antepartum eclampsia at term in a primigravida aged 23. Patient was admitted at 9 P.M. on Sept. 8th, 1929, in deep coma. There was a history of her having had five fits, beginning five hours before admission. The urine became solid on boiling, œdema was present. The B.P. was 140/110. She improved under treatment, and on the 9th the fits ceased, she having had nine more after admission. She was conscious and commenced in labour that day. She was delivered of a stillborn child on the next day, labour having taken 14 hours. On the 11th complete suppression of urine became evident. The usual medical treatment was given. but the patient died on the 12th. Post-mortem examination was refused by relatives.

CASE 36.—A case of ante- and intrapartum eclampsia at 38 weeks in a primipara. Patient was sent in as a pre-eclamptic on Sept. 26th, 1929. with a history of five weeks' severe albuminuria, and during the pregnancy she had had several attacks of antepartum hæmorrhage. On admission she was vomiting, complaining of dimness of vision, epigastric pain, and blood was found in the urine in addition to albumin. She was given morphia, a purgative, and an enema. and at 8 A.M. on the 27th she had her first fit, and probably began in labour about the same time. Routine treatment was immediately commenced. The fits ceased at 7 P.M., and her condition improved until about 3 A.M. on the 28th, when the heart became irregular. The patient collapsed and died at 4.30 A.M. Post-mortem refused by relatives.

CASE 38.—Antepartum eclampsia at 24 weeks. Patient, a 3-para aged 24. was admitted at 7.30 A.M., Oct. 11th, 1929, in coma. There was a history of eight weeks' severe albuminuria. and fits at short intervals for five hours before admission. On admission the urine became solid on boiling, the temperature 102·4° F. Routine treatment was commenced. She had nine fits between 7.30 A.M. and 8.30 A.M. when the fits ceased. Despite the cessation of the fits, her condition became worse, pulmonary œdema being a prominent feature. Continuous oxygen was administered, but she died at 6.20 P.M. Post mortem refused by relatives.

CASE 43.—Antepartum and intrapartum eclampsia at 30 weeks in primipara aged 36. Patient was admitted at 3.45 A.M., Jan. 20th, 1930, with history of severe albuminuria for 10 days. She had, however. refused hospital treatment. Three fits occurred before admission and coma was present. Routine A treatment was begum on admission. By 11 A.M. she had had 13 more fits. Intravenous glucose was then given, after which she had three fits, the last being at 2.4 A.M. The glucose was repeated at 8.30 P.M. At 9.30 P.M. severe vomiting began. The temperature began to rise and she became collapsed, necessitating stimulants. Pulmonary œdema was present. Uterine contractions became evident about 8.30, and the temperature rose to 107°. The patient died at 2.40 A.M. on Jan. 21st, 1930. Post-mortem refused.

CASE 58.—Antepartum and intrapartum eclampsia at 30 weeks in 2-para aged 27. Patient was admitted unconscious at 10.30 A.M., August 23rd. 1930, with a history of sudden onset of blindness, severe headaches, and convulsions about 10 A.M. She had had three fits before admission. The urine was found to become solid on boiling; the B.P. was 160/120. Patient was conscious. Routine treatment was commenced. but the glucose was not given till later. She had 14 fits after admission to hospital, 7 before and 7 after administration of the glucose. The last fit was at 6.20 P.M. At 7.45 P.M. an extra colon lavage was given. About this time it was found that she had commenced in labour. At 9.15 the temperature rose to 107·4°, and the patient collapsed. Stimulants and oxygen were given, but she died at 8.10 on the next morning.

Post-mortem.—The liver was small and jaundiced in colour. Microscopically the cells showed much fatty degeneration, and there was some pericellular fibrosis. The kidneys were enlarged and deep red in colour. There was much desquamation of cells and loss of nuclei, both in the tubules and glomeruli. There were numerous casts.

CASE 91.—Intrapartum eclampsia at 31 weeks in a primipara aged 31. Patient was admitted on Oct. 8th, 1931, at 2.35 A.M., in a collapsed condition, with a history of five fits occurring in the five hours previous to admission. She had a weak irregular pulse. Temperature 104°. Blood pressure 140/90, the urine being solid on boiling. The routine treatment was commenced. She appeared to improve following the glucose saline at 3.15 A.M., and she had one further fit only, at 3.25 A.M. She collapsed again, however, and died at 3.40 A.M. Post-mortem refused.

Summary

A conservative treatment of eclampsia has produced an improvement in results at St. Mary's Hospitals, Manchester. the maternal mortality having been reduced to 7 per cent. in a series of 100 consecutive cases.

THE PHYSIOLOGY OF PROTEINURIA

AND ITS CLINICAL SIGNIFICANCE

BY PHYLLIS M. TOOKEY KERRIDGE,[*] M.SC., PH.D. LOND.

LECTURER IN THE DEPARTMENT OF PHYSIOLOGY AND BIOCHEMISTRY, UNIVERSITY COLLEGE, LONDON

AND

L. E. BAYLISS, PH.D. CAMB.

BEIT MEMORIAL FELLOW

(From the Department of Physiology and Biochemistry, University College, London, and the Medical Unit, The London Hospital)

URINE from a healthy kidney does not normally contain more than a trace of protein, although Maclean [1] and others have found proteinuria in about 5 per cent. of apparently normal men. Proteinuria may be due to purely physiological conditions, especially those leading to renal venous stasis and to stimulation of the sympathetic nervous system. In disease, proteinuria is associated with nephritis, nephrosis, and other diseases of the kidneys, with cardiac disease associated with venous congestion, the "toxæmias" of pregnancy, fevers, &c. In many of these cases it has been demonstrated satisfactorily that the protein in the urine is identical with the albumin and globulin of the plasma, and it has been assumed that the kidneys allowed these to leak through, either because of local damage, or because of the poor conditions under which they were made to function. In recent years it has been several times suggested that it may be in some cases the proteins which are at fault, instead of the kidneys. Thus Epstein [2] has suggested that nephrosis is primarily a metabolic disorder, in which the proteins have become a waste product, and he has introduced the term "diabetes albuminuricus." Munk, Benatt, and Flockenhaus [3] consider that in lipoid nephrosis there is a change in the physico-chemical characters of the body colloids, and that the renal changes are secondary. Thomas, Schlegel, and Andrews [4] have suggested that the proteins excreted in nephritis are primarily derived not from the serum but from the liver, although serum proteins may accompany the others at later stages. Andrews, Thomas, and Welker [5] in a later paper state that "the presence of serum proteins in the urine in nephritis is due to their combination with other nitrogenous fractions of tissue origin, some of which are highly toxic." It is their belief that "this combination acts as a detoxicating mechanism, and that the elimination of this protein by the kidneys is due to alteration of normal serum proteins by their combination with other split products which render them foreign to the circulation."

The present paper is not concerned with the evidence on which these theories are based, but with the underlying idea which is common to all of them

---

[*] Receiving a part-time grant from the Research Fund of the London Hospital.

—namely, that a normal kidney can excrete a protein which is "foreign" or obnoxious to it. This opinion is widely held, in spite of the very great difficulties in explaining such a property according to the present knowledge of renal physiology. It is well expressed in the following translation from Volhard's treatise on nephritis [6]:—

> "It is one of the many mysterious performances of the kidney epithelium that it does not hold back foreign kinds of protein, but excretes them with the urine."

This belief seems to have been based on the fact that an excess of ingested egg albumin may escape digestion and appear in the urine. The original observation is said by Claude Bernard [7] to have been made by Berzelius about 100 years ago. There are several papers in the literature of 50–70 years ago studying the excretion of egg albumin injected intravenously into animals, and discussing whether it escaped through the glomerular membranes or the tubular epithelium. More recently there have been many studies on the excretion of hæmoglobin, and a few showing that Bence-Jones protein was excreted when injected intravenously into dogs.

In spite of the above evidence that foreign proteins are excreted by the kidney, the matter seemed to be so important clinically, and so difficult of physiological explanation, that it was decided to investigate the matter further. Experiments have been performed both on anæsthetised cats and rabbits, and on isolated kidneys of dogs, which were perfused with defibrinated and oxygenated dogs' blood by means of a pump. In this way observations confined to one animal were avoided, and a watch could be kept for effects due to the nervous system or to organs other than the kidneys. The "pump-lung-kidney" preparations were made in duplicate, so that the two kidneys of one dog could be perfused simultaneously and independently, one kidney being used for experimental, the other for control purposes. It may be stated at once that the experiments on the whole animals and on the isolated kidneys gave identical results. Various proteins dissolved in 0·9 per cent. NaCl were added to the circulating blood, through a cannula in the jugular vein in the whole animals, and by simple addition to the blood reservoir in the isolated preparations. Proteins were chosen, the molecular weights of which were fairly certainly known. It was fortunate that Svedberg and his colleagues [8] had determined so many in the last five years, with particular reference to their stability at various hydrogen-ion concentrations and temperatures. His method is based on a study of the sedimentation of the protein when rapidly centrifuged. It also allows him to obtain an approximate figure for the radii of those molecules which are spherical, and a factor of dyssymmetry in other cases.

The results are summarised in the accompanying Table, which also gives Svedberg's figures for the molecular weights and molecular radii.

It will be seen at once that it is only the proteins with the smaller molecular weights and the smaller *molecular radii* which are excreted. Since it happens to have been only the smaller proteins which were studied by previous workers, a misconception has arisen. The barrier seems to correspond to a molecular weight of 68,000, and a molecular size of somewhere about 2·5 μμ. *Hæmoglobin* has been included in both classes, as it is only excreted when present in a concentration above a certain threshold, as has also been shown by previous workers. It is not apparent why hæmoglobin in high plasma concentration should be excreted, while serum albumin in equivalent concentration is not. There are possibly anomalies about the borderline, and as neither of these proteins has a symmetrical molecule it may be due to some difference in molecular shape. The serum proteins used were human, horse, ox, cat, and dog. The proteins were not separated from one another or purified, but the whole "foreign" serum was added. In no case was the "foreign" serum protein excreted.

Summary of Results

Protein.	Molecular weight.	Molecular radius.
Excreted.		
Gelatin	35,000	?
Egg albumin	34,500	2·17 μμ*
Bence-Jones	35,500	2·18 μμ
Hæmoglobin	68,000	(Not spherical).
Not Excreted.		
Hæmoglobin	68,000	(Not spherical).
Serum proteins—		
Albumin	67,500	(" ")
Globulin	103,800	(" ")
Casein	188,000	(" ")
Edestin	208,000	3·94 μμ
Hæmocyanin (Helix)	5,000,000	12·00 μμ

* 1 μμ = 1 millionth of a millimetre.

Such proteins as were excreted were concentrated, the concentration ratio—urine/plasma—being about 5. There was no evidence that the elimination of moderate amounts of protein affected the renal function. Nevertheless, it is possible that very prolonged excretion of large amounts of protein might interfere with normal renal function, which might account for experiments by previous workers who detected serum proteins being excreted at the same time as egg albumin, and would also suggest that the renal insufficiency sometimes, but not always, associated with Bence-Jones proteinuria, may be a secondary effect.

We therefore conclude that proteins are excreted or are not excreted by the normal kidney according to their physical size, and not according to their chemical nature or biological origin. This is a finding which simplifies the approach to the study of the excretion of protein in disease. Svedberg has shown that some of the proteins with large molecular weights can be broken up into units of lower molecular weight, under various conditions of salt concentration and acidity, and he regards a unit of molecular weight of 35,000 as common to proteins. It is therefore not inconceivable that some such change might occur in disease, with subsequent excretion of the smaller molecule. We are proceeding to investigate the question as to whether any of the proteins found in human urine in disease are excreted by a normal kidney. Those purified by dialysis from the urine of patients with cardiac lesions and venous congestion do not pass through a normal kidney. Our observations on nephritic urinary proteins are not yet numerous enough to publish.

A full account of the work referred to in this paper, with experimental details, will be published elsewhere, together with a histological note by Dr. Dorothy S. Russell.

SUMMARY

Several theories of renal disease depend on the assumption that kidneys can excrete "foreign" or obnoxious proteins. Experiments on animals have shown that only proteins with molecular weights less than 68,000 are excreted. Proteins with larger molecular weights, including serum proteins of other species, are not excreted. Hæmoglobin, with a molecular weight of 68,000, is peculiar in that it is excreted when its concentration in the plasma exceeds a certain value. Whether or not a protein

is excreted by the kidney depends on its physical properties, and not on its chemical nature or biological origin.

Clinical and Laboratory Notes

ARTIFICIAL PNEUMOTHORAX

SOME RESULTS OF OUT-PATIENT TREATMENT

BY V. S. HODSON, M.D., OXF., F.R.C.P. LOND.
PHYSICIAN, VICTORIA PARK CHEST HOSPITAL

AND

R. S. JOHNSON, M.D., M.R.C.P. LOND.
PHYSICIAN TO OUT-PATIENTS, VICTORIA PARK CHEST HOSPITAL; CASUALTY PHYSICIAN, ST. BARTHOLOMEW'S HOSPITAL

IN a report published in THE LANCET (1931, i., 1028) we dealt with the results of treatment of 26 cases of pulmonary tuberculosis at an out-patient artificial pneumothorax clinic at Victoria Park Hospital during 1930. These cases have been further observed and, with others, form a group of 55 treated during 1931.

In our previous report we drew special attention to the relatively minor importance of the mechanical aspect of the treatment, and we have again been impressed by the necessity for careful review of the patient as a whole, and consideration of symptoms and physical signs at each visit. Only by such constant supervision can the full benefit of the treatment be obtained.

An analysis of the cases and results of treatment is given below.

Total cases, 55: male, 22; female, 33.
Average age: males, 30·1 years; females, 24·5 years.
Age-groups.—Male: 10–20, 1; 21–30, 11; 31–40, 7; 41–50, 3. Female: 10–20, 8; 21–30, 22; 31–40, 1; 41–50, 2.
Extent of lung disease: unilateral, 41; right, 17; left, 24; bilateral, 14.
Side of pneumothorax: right, 25; left, 28; bilateral, 2.
Prognosis: good, 35; doubtful, 9; poor, 11.
Working or fit to work: 34.
Unfit to work: 21.
Weight: stationary, 35; gain, 10; loss, 10.
Sputum: test for tubercle bacilli positive, 10; sputum absent, or T.B. negative, 45.
Effusion: serous, 18; purulent, 2 ("sterile" T.B. present) (1 spontaneously absorbed).
Adhesions: operated on, 7; not operated on, 31.
Admitted to hospital or sanatorium: 9.
Average duration of pneumothorax to end of 1931: 22 months.
Duration in years: 1 year, 23; 2 years, 18; 3 years, 12; 4 years, 2.
Intervals of refills: 1 week, 2; 2 weeks, 15; 3 weeks, 10; 4 weeks, 10; 5 weeks, 5.

In a disease the course of which is so varied as is that of pulmonary tuberculosis, figures must necessarily be interpreted with caution, the more so if the series of cases is small. Nevertheless, the fact that of the 55 cases 34 remain free from symptoms of illness and are either in actual employment or fit to work appears to us, in the circumstances, a satisfactory result. Routine examination of sputum has given a positive result in ten cases only during the year, and in two of these the test has since become negative. The removal of a large proportion of patients from the positive to the negative group must be regarded as a definite advantage to the community. In 29 of the present series both cough and sputum are absent.

Pleural effusion of some degree was again common, complicating 20 cases, of which 18 were serous and 2 purulent, containing tubercle bacilli, but sterile on culture. Fluid was found to appear more frequently among those patients in whom adhesions prevented a complete collapse of the lung. Thus, of 38 such cases with adhesions, effusion occurred in 17 (45 per cent.), while of 15 cases free throughout from adhesions, in 1 only (6·3 per cent.) was fluid found. In the remaining 2 cases of the series an effusion had followed the division of adhesions previously present. These results lend support to the conclusion of S. R. Gloyne,[1] from experimental studies and post-mortem examinations, that the probable cause of effusion complicating pneumothorax is the stretching and rupture of an adhesion at a point at which tubercle bacilli can be liberated into the pleural cavity.

In the majority of cases the occurrence of effusion caused no serious interference with the treatment; often the degree of collapse was thereby improved, while the intervals between refills could be subsequently lengthened. As regards prognosis, there appeared little to choose between those cases with and those without effusion. Of 18 cases with serous effusion the results were good in 12 and doubtful or poor in 6, while of the 35 cases without effusion 23 did well and 12 had a doubtful or poor prognosis. Five cases at some stage of their course required air-replacement.

In 4 cases effusion was followed by an obliterative pleurisy, creeping slowly upwards from the diaphragm with re-expansion of the lung below a fluid level, the effusion being finally absorbed or reduced to a small encysted or loculated collection, surrounded by densely thickened pleura and fibrotic lung. In each instance, although refills had to be abandoned, the final condition of the patient was good.

Nine patients were admitted to hospital or to sanatoriums during the year; 3 for division of adhesions, 4 to sanatoriums as an accessory to treatment and to help favourable progress, and 2 because the condition was deteriorating.

Pneumothorax was discontinued in 17 cases. In 8 of these it was considered safe to allow re-expansion of the lung, as the disease appeared clinically arrested, the average duration of the collapse being two years ten months. The reason for discontinuing the pneumothorax was fluid in 4 cases; extension of disease to the other lung in 4; and in 1 case interference with the circulation resulting in cardiac distress and dropsy, which were relieved on ceasing the refills.

APPARATUS FOR THE MICRO-ESTIMATION OF BLOOD CHOLESTEROL

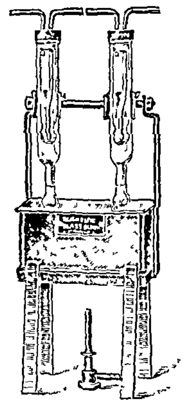
BY R. L. DUTTON
SENIOR TECHNICIAN, PATHOLOGICAL LABORATORIES, THE ROYAL HOSPITAL, WOLVERHAMPTON

IN view of the importance of following the blood cholesterol in the treatment of diabetes some method of estimating it, using only small quantities of blood, has become desirable.

In 1924 Leiboff[1] described a method demanding the use of only 0·25 c.cm. blood, an amount easily obtainable by finger puncture. In Leiboff's method the blood is taken up into a 0·25 c.cm. pipette and discharged on to a disc of filter paper, which is thereafter extracted with chloroform in a special form of still. The method has the advantages of being simple, quick, and of requiring only a small amount of blood; further, owing to the fact that the extraction and estimation are performed in the same tube, there is no loss of the cholesterol under estimation. It has, however, certain disadvantages dependent upon the fact that the special Leiboff extraction tube is connected to the special still by means of a cork; the distillation is performed over a water bath and in using the apparatus it has proved very difficult to prevent water due to steam condensation soaking through the cork and spoiling the chloroform extract.

---

[1] Tubercle, 1926, vii., 424.



The apparatus described below is a modification of the original Leiboff tube designed to eliminate this disadvantage; it has the further advantage of doing away with the necessity for the special still, a fairly expensive piece of apparatus.

The *apparatus* consists of a tube 6 in. long and 1 in. in diameter; it is constricted at the lower end and terminates in a bulb after the manner of the Folin tube. The bulb below the constriction is graduated accurately to a total content of 5 c.cm. The tube may be fitted with a side-tube to allow of the escape of the chloroform vapour, but this is not necessary. Suspended in the upper part of the tube is a simple condenser.

Method.—The blood specimen may be collected from a finger prick straight into the 0·25 c.cm. pipette or alternatively oxalated blood may be used; it is discharged on to a filter-paper disc ¾ in. in diameter cut from Whatman filter paper 1/16 in. thick; the discs should be ether-extracted in bulk before use. If the apparatus has not a side-tube two small crescents may be "nibbled" from the edge of the disc to allow free passage of the chloroform vapour. In order to get rid of water the disc with the absorbed blood is dried by gentle heating for half an hour at between 40° C. and 50° C. A little less than 5 c.cm. pure dry chloroform is poured into the extraction tube and the dried impregnated filter-paper disc is dropped into the tube where it remains supported just above the constriction. The condenser is placed in position and the tube immersed to the level of the chloroform in a bath of boiling water. Extraction has been found to be complete in 20 minutes, but half an hour is usually allowed. The tube is removed from the bath, wiped dry, and the condenser and disc are removed; when the tube has cooled to room temperature chloroform is added exactly to the 5 c.cm. mark. Estimation is performed in the usual way making use of the Liebermann-Burchard reaction; 5 c.cm. of a standard solution of cholesterol containing 0·4 mg. cholesterol per 5 c.cm. is placed in a similar tube; to both standard and test are added 2 c.cm. acetic anhydride and 0·1 c.cm. concentrated sulphuric acid. Cork stoppers are inserted, the tubes are then inverted twice to mix well, cooled for half a minute in cold water, and set aside in the dark for ten minutes for the colour to develop. Comparison is made with the colorimeter, the standard being set at 10 or 15 depending on the intensity of colour of the unknown. Calculation:—

$$\frac{\text{Reading of standard}}{\text{Reading of unknown}} \times 160 = \text{mg. per 100 c.cm. blood.}$$

TABLE I

Experiment No. ..	1	2	3	4
Amount of cholesterol—				
On disc	in mg. 0·1	0·2	0·5	1·0
In control	,, 0·1	0·2	0·5	1·0
Colorimeter reading—				
Of control	in mm. 15·0	15·0	15·0	10·0
Of extract (using Leiboff tube) ..	,, 14·9	14·9	15·1	10·0
Of extract (using modified tube) ..	,, 14·8	15·0	14·9	10·1

The standard solution of cholesterol should be kept in the form of a concentrated 0·08 per cent. solution and diluted 1 in 10 for use.

Table I. indicates the accuracy of the method. Varying amounts of cholesterol were absorbed on to the discs and extracted, and the extracts were compared with controls containing the same amounts. Table II. shows comparative estimations by the methods of Bloor[2] and of Myers and Wardell.[3] It will be noted that the readings obtained by the Leiboff method are higher than those obtained by the method of Myers and Wardell. This fact was noted by Leiboff in his original description of the method and is probably due partly to loss in transferring the plaster-of-Paris from the mortar to the extraction thimble, and partly to unequal percolation of the plaster-of-Paris mass by the chloroform.

TABLE II

Experiment No.	1	2	3
Cholesterol content of blood in mg. per cent. by method of—			
Bloor	168	160	235
Leiboff, using modified tube	164	152	210
Myers and Wardell	132	128	182

I am indebted to Dr. S. C. Dyke, director of the department, for his kind assistance. Further particulars with regard to the apparatus described are obtainable from the makers, the Scientific Glass-blowing Co., 95, Gray's Inn-road, London, W.C.1.

THE URETERIC LAMP AND ITS USES

BY TERENCE MILLIN, M.CH. DUB.,
F.R.C.S. ENG. AND IREL.

HON. ASSISTANT SURGEON, ALL SAINTS' HOSPITAL FOR GENITO-URINARY DISEASES, LONDON

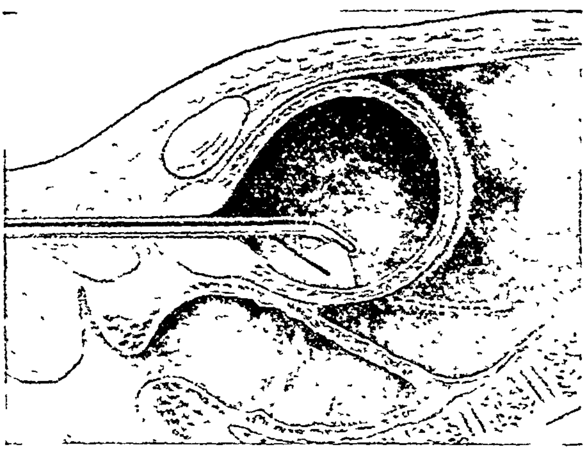
THE great strides made in urological diagnosis in recent years have led to the recognition of many lesions of the ureter or upper urinary tract which call for ureteric surgery. Sometimes the identification of the ureter after abdominal section is by no means easy, especially when one is dealing with the pelvic portion of the tube. Some operators pass a ureteric catheter and rely on palpation, but the illumination of the ureter obtained with an intra-ureteric lamp is a great advantage. Such an instrument is useful, not only where the ureter is the avowed object of the surgical attack, but in many cases where extensive peri-ureteral dissection may be necessary, as in Wertheim's radical hysterectomy or Miles's abdomino-perineal resection of the rectum. The following case illustrates the use of a type of transilluminator whose advantages are not, I think, sufficiently appreciated.

The patient, aged 56, was referred on account of attacks of renal pain recurring every few months during the preceding nine years, associated occasionally with slight hæmaturia. These attacks began with pain in the right loin, which radiated backwards to the renal angle. They were seldom severe, and rest in bed led to their prompt disappearance. There were no other urinary symptoms. Clinical examination was negative. Radiography revealed a small shadow in the right iliac fossa, sufficiently close to the probable line of the ureter to raise the suspicion of urolithiasis, and immediately below the right sacro-iliac synchondrosis the shadow of a small pin was seen. A large opaque ureteric catheter was readily passed to the renal pelvis without obstruction and clear urine. subsequently proved to be sterile, was withdrawn. Radiographically, the shadow in the iliac fossa was seen to be 1 cm. outside the line of the ureter. The pin overlay the catheter directly. Intravenous urography showed kidneys functionally intact, but slight pyelectasis was present on the right side with a prolonged emptying time. In all the films the pin overlay the pelvic ureter and, in all, the right ureter was indistinctly outlined in the iliac fossa, suggesting a spasm in correlation with the other findings.

The patient was sceptical as to the possibility of his having swallowed a pin unwittingly. More questioning revealed the fact that after meals there was usually some discomfort in the right iliac fossa. A provisional diagnosis of peri-ureteritis due to a foreign body in the vermiform appendix was made and laparotomy was advised.

After induction of anæsthesia (gas-oxygen-ether). the ureteric transilluminator (described below) was passed through a Buerger operating cystoscope. The abdomen was opened through a right paramedian incision and a long appendix. hanging quite freely into the pelvis, was exposed. It was removed and proved to contain a small steel pin in the distal extremity, the point of the pin directed against the tip of the viscus. The ureteric lamp was switched on and, with the intestines packed out of the way, the ureter was clearly defined and examined. The two calcified glands seen radiographically were felt lateral to the ureter but, in direct contact with the tube, were seen two or three small discrete glands. As there was no apparent peri-ureteric thickening, dissection was deemed unnecessary and the abdomen was closed. Eight months have elapsed since the operation and there has been no recurrence of the renal pain. All the dyspeptic symptoms have likewise disappeared. It appears probable that the appendicular glands in the ileocæcal angle were causing ureteric spasm with varying degrees of upper urinary tract obstruction.

The ureteric lamp or transilluminator used in this case was introduced more than ten years ago by Mr. Canny Ryall. It consists (see illustration) of a small lamp mounted on a long flexible insulated wire, similar in appearance to the commonly employed ureteric catheter. The lamp itself is covered save for two small windows through which the light is projected. A length of cord connects the lamp with an accumulator. and interposed on the circuit is a switch. The ureteric portion is made in various sizes from 7 F. to 15 F., all readily introduced through an operating cystoscope. The actual passage of the transilluminator takes but two or three minutes and entails no difficulty to those versed in the technique of ureteric catheterisation. The larger sizes are useful for the illumination of vesical diverticula.



One warning is perhaps necessary. It is essential to be sure that the terminal portion containing the lamp is well screwed home, since a loosely fitting junction might well lead to the lamp being left behind on withdrawal of the catheter. I have not heard of such an accident, but it appears to be a possibility. The instrument is withdrawn when the ureter has been identified and, as a routine, the integrity of the equipment should be verified.

I am indebted to Mr. Canny Ryall for permission to reproduce the accompanying illustration, which first appeared in his " Operative Cystoscopy."

REVIEWS AND NOTICES OF BOOKS

Pseudo-Ulcus Ventriculi

By H. HANSEN. Copenhagen: Levin and Munksgaard. 1932. Pp. 430.

Dr. Hansen has written a book of over 400 pages based upon a careful analysis of 85 patients suffering from gastric ulcer or presenting symptoms similar to those of ulcer. At the same time he has reviewed fully the extensive literature upon this subject; the list of references occupies 30 closely printed pages. The clinical picture of gastric ulcer may be so variable that any long-standing indigestion is liable to be suspect; on the other hand many causes may produce similar symptoms. Dr. Hansen has paid particular attention to tuberculosis, and believes that a large proportion of so-called simple dyspepsias have their origin in tuberculosis. All workers will agree that benign tuberculosis of the lungs is able to cause disorders of gastric function and symptoms of gastric pain, but the frequency with which such dyspepsia offers diagnostic difficulties may vary considerably in different countries. In England the differential diagnosis of phthisis from gastric ulcer is not so common a problem as it would appear to be in Denmark.

To those specialising in digestive disorders Dr. Hansen has given useful help. He has collected valuable information from the scattered literature, and has supplied instructive full case-histories, although the numbers he is able to quote are too small to justify general conclusions. The inconstancy of symptoms on which he relies as a point against the probability of gastric ulcer is often found in proved cases of this disease. But his discussion of the symptoms which make unlikely the presence of an ulcer will supply a convenient summary of the knowledge which has been gained by clinicians of wide experience.

Abdominal Cavity and Peritoneum

A Clinical Study. By EDWARD M. LIVINGSTONE, B.Sc., M.D., Associate Visiting Surgeon, Bellevue Hospital. New York: Paul Hoeber. 1932. Pp. 866. $15.

THE phenomena of abdominal disease are the result of the relations of the viscera to the abdominal walls and more distant parts of the body, and are explainable largely on embryological and neurological grounds. The object of the author has been to help the clinician by placing the mechanism of symptoms upon a rational basis, and in pursuit of this aim he has divided his subject up into chapters in which are considered separately the cavity. the wall, the gastro-intestinal tract. visceral neurology, and so on. The book has a refreshing and stimulating quality; nearly every topic is presented from an unfamiliar aspect. The arrangement of matter, however, leads to much overlapping, and yet a sense of incompleteness in individual sections. For example, on page 593 a section is headed, "Reflexes initiated from within the stomach and expressed elsewhere." This is literally true, since a few lines further down we are referred to page 213 for the points of tenderness and hyperalgesia associated with peptic ulcer; we are then asked to turn to page 69 to learn what Sale's reflex is; and on proceeding to page 69 and satisfying ourselves about diaphragmatic spasm, we are told that it can also be detected by Litten's sign, an account of which may, it is said, be found in the "section on eponyms." This may indeed be so; we ourselves did not pursue the investigation further. It is common throughout the book to find a reference to signs or symptoms of which the explanation is given elsewhere. Even this confused arrangement of the material does not detract much from the value of a book which contains such useful information. A particularly good chapter is that entitled The Clinical *Interpretation of Viscerosensory Phenomena or Skin* Signs, to which Dr. Livingstone has given much study. On the physiological side there are important omissions: the phenomena of secretion, the influence of endocrine glands on abdominal phenomena, the physio-pathology of intestinal obstruction. A curious feature is a collection of more than 1000 examination questions which occupy 100 pages. An attractive collection of facsimile reproductions of some of the epoch-making contributions to abdominal diagnosis is included.

Les maladies organiques du faisceau de His-Tawara

By Ivan Mahaim, Privat-docent à la Faculté de Médecine de Lausanne. Paris: Masson et Cie. Pp. 586. Fr.80.

This book is the outcome of years of original research on the complicated pathological changes which can affect the bundle of His-Tawara, and is especially directed to furnish histological proof of lesions demonstrated by the electrocardiogram. An effort has been made to correlate the clinical with the pathological aspect of the subject, and to eliminate much that has up till now been hypothetical. The author has worked to distinguish not only the nature of the lesion but its localisation and extent. The first part of the book is devoted to the anatomy and physiology of the bundle and to the methods used for examination, both graphic and histological. In the anatomy section the vascular supply is treated in great detail, since it would appear that changes affecting this explain the majority of the disorders to which the bundle is subject. The graphic method is given in great detail so as to make it possible for everyone to follow clearly its practical applications.

The second part of the book studies the clinical and anatomical findings. In many cases a detailed clinical history is given, illustrated by electrocardiographic tracings, and in some cases X ray photographs or orthodiagrams; the subsequent post-mortem findings are related and illustrated with microphotographs of serial sections of the bundle. These observations appear to cover practically all the known types of disordered rhythm, and many hitherto unpublished observations are included.

The third section seeks to demonstrate synthetically the relation between the lesion and its causal factor in coronary lesions, inflammatory valve lesions, and congenital myocardial defects. An important chapter is devoted to coronary artery disease and cardiac infarction, and its relation to the bundle. It is shown how coronary lesions can provoke two diametrically opposite disorders of rhythm which may succeed each other—namely, hyperexcitation as the result of the irritation of ischæmia, and inhibition as the result of scarring. The syndrome of septal endocarditis is an interesting condition of obvious clinical importance. Finally, the author reviews congenital defects in relation to the bundle, and ends with a chapter on prognosis and therapy. A valuable bibliography is appended.

Statistical Methods for Research Workers

Fourth edition. By R. A. Fisher, Sc.D., F.R.S., Chief Statistician, Rothamsted Experimental Station. Edinburgh and London: Oliver and Boyd. 1932. Pp. 307. *15s.*

Dr. Fisher's aim in this monograph was, without entering unduly into the mathematical theory of these statistical methods, to embody the latest results of that theory, presenting them in the form of practical procedures appropriate to those types of data with which research workers are actually concerned. The rapid demand for a fourth edition is sufficient evidence that the value of his book has been appreciated in spite of its difficulties; for it is not an easy book for the layman or even for the trained statistician. The changes in this edition are not very extensive. Amongst them are the addition of a note on the historical origin of the statistical theory underlying the methods presented, and the consideration in more detail of the analysis of covariance. Dr. Fisher is to be congratulated on having produced, in addition to his important contributions to statistical theory, a book which is obviously assisting research workers to interpret their data.

1. Outline of Comparative Embryology

By Aute Richards, Professor of Zoology in the University of Oklahoma. London: Chapman and Hall, Ltd. Pp. 444. *30s.*

2. Text-book of Human Embryology

By Cleveland S. Simkins, Ph.D., Associate Professor of Anatomy in the Medical School, University of Tennessee. Philadelphia: F. A. Davis Company. Pp. 469. $4.50.

1. An excellent book, written by one who has thoroughly mastered his subject. The book is intended for students and other workers in biology and general comparative embryology, but no medical student interested in the biological side of his work could fail to learn and benefit from a study of this orderly and comprehensive volume. The book is, of course, not confined to chordate embryology; the first part deals with the actual early developmental phases in numerous types illustrating general features, and the second part deals with questions associated with embryology, such as germ-cells, the germ-layer theory, recapitulation, asexual and parthenogenetic reproduction, pædogenesis and neoteny, polyembryony, the determination problem, and ecological control of invertebrate larval types. The illustrations are excellent and appropriate, and the glossary and bibliography adequate.

2. This book, among features not commonly found in works of this sort, gives us many new figures. These include some which are not easily available to the ordinary student. The sections dealing with purely histological matters are good, even though they present the reader with a multiplicity of long

names; but we confess to some disappointment in the other parts of the book. The author seems to have views concerning implantation and villous formation which are not exactly in accord with those held in this country. Among the figures we detected some irregularities: for example, a diagram of the sternum shows this possessing a central unpaired bar in addition to the usually accepted lateral structures, but no mention of such a thing is to be found in the text. Again, the account of division of the ventricular region of the heart does not seem to us to be intelligible. In this connexion we hope soon to have seen the last of those absurd figures of these parts, which are taken from Kollmann—but hardly from the normal embryo. Prof. Simkins has done much work on the histological differentiation of the genital glands, and gives a good account of the developmental processes within the genital system.

A General History of Nursing

By L. R. SEYMER, M.A. Oxf., S.R.N. London: Faber and Faber. 1932. Pp. 307. 12*s.* 6*d.*

Mrs. Seymer's book, which she describes modestly as a historical sketch, is closely packed with information. In a succinct manner, and with a wealth of references in testimony of anxious research, the classic origins of the nurse's calling are sketched, and the early Christian, monastic, and mediaeval developments set out. In all this the author is going over old ground, but the interesting story is well composed, and the sources of information are recorded, so that anyone interested in a particular phase can supplement what is given. When the history reaches the nineteenth century we have a record of the early nursing sisterhoods of particular value, for the archives here are not easy of access, and there is no widespread familiarity either with the cause and spirit of their origins, or with the part that they played 100 years ago, and are still playing, in the progress of the nursing profession. Florence Nightingale's work receives again the tributes which can never be too often repeated, and the fact that with the opening of the Nightingale school the era of nursing, as we now understand it, definitely began, is brought out.

We now arrive at modern history, and this is told with consistent adherence to the method adopted in the earlier part of the book—that is to say, that the author is fully descriptive but never critical. The plan of education, the development of training schools, the arrival of State recognition, and the institution of internal organisation are fully dealt with, and the multiplicity of work, now grouped under the common heading of "public health service," is carefully analysed, the information being made both interesting and valuable by its international character. But how the working of the educational scheme and of the training schools has succeeded is not mentioned. Nor is there any suggestion that either may be capable of improvement or expansion. The resolve to be descriptive and not critical is maintained throughout.

The least satisfactory sections are those dealing with insurance and pension schemes and with working hours. The former indicates (p. 237) the superannuation conditions which obtained in this country before April, 1930, when the poor-law hospitals were transferred to local authorities, rather than those now in force. As to hours of work, it is hardly true, as is here stated, that "in most hospitals in England . . . the 56 hour week already prevails" (p. 239). The average weekly hours (excluding all meal-times) in the representative group of hospitals answering the questionnaire of THE LANCET Commission on Nursing (see p. 247 of their Final Report) were: 50 to 54 hours, 15 per cent.; 55 to 59 hours, 50 per cent.; 60 to 64 hours, 28 per cent.; 65 to 69 hours, 7 per cent.

This is an interesting book and the outcome of real research, much of which has been made possible by the use of the library at Geneva belonging to the International Council of Nurses.

Schizophrenia

By HELGE LUNDHOLM, Ph.D., Associate Professor of Psychology, Duke University. Durham, N.C.: Duke University Press. 1932. Pp. 117. 5*s.* 6*d.*

THE general method of this work is that which has been until lately characteristic of much American psychiatry. Prof. Lundholm attempts to interpret the morbid development of the schizophrenic patient as being the "life-situations" of a specially responsive personality; he considers it mainly in the light of McDougall's general doctrine of psychology. The virtue of the method lies in its emphasis on the interplay of disposition and environment, its weakness in the superficial broadness of survey and reliance on explanation in terms of comprehensible behaviour. It offers rather facile speculations about accepted data and these speculations do not suggest further lines of inquiry. The discussion of delusions and of "scattered" thinking in this study is surprisingly out of touch with the intricacies of modern psychopathology. The author has clearly spent much time in the observation of patients and has succeeded in fitting most of their behaviour into a complete framework of theory. Such interpretative studies are admittedly more satisfying to many psychiatrists than is a recognition of the great gaps in present knowledge; a patient willingness to collect further observations or to test dubious but stimulating hypotheses is more rare. Dr. Lundholm offers nothing astonishing and nothing profound but much that is interesting. His style is not lucid; such phrases as "the contex of a complex" and "this son of man" irritate and mystify the reader.

Anatomie des lymphatiques de l'homme

By H. ROUVIÈRE, Professor of Anatomy in the Faculty of Medicine of Paris. Paris: Masson et Cie. 1932. Pp. 489. Fr.150.

THIS book represents the information of to-day concerning the lymphatic systems of man, set forth by a well-known authority. Prof. Rouvière has devoted years to this study, and to the collection of results obtained by other workers; the present work, therefore, has value for the clinician as well as for the anatomist. The subject does not lend itself to a description which communicates the author's enthusiasm to the reader, for it would be idle to pretend that continuous accounts of groups and subgroups of nodes with their attendant collector and drainage systems, do not in their repetitions become somewhat wearisome. Here at least one is fortified by the knowledge that one is receiving of the best. The brief descriptions in English text-books are in general agreement with the detailed statements made in this monograph, which also deals with variations not found in text-books. The recent work of Kiss and Botar on the relations between the lymphatic channels and the vegetative nerve-plexuses to much overlapping, and yet a sense of incompleteness in individual sections. For example, on page 593 a section is headed, "Reflexes initiated from within the stomach and expressed elsewhere." This is literally true, since a few lines further down we are referred to page 213 for the points of tenderness and hyperalgesia associated with peptic ulcer; we are then asked to turn to page 69 to learn what Sale's reflex is; and on proceeding to page 69 and satisfying ourselves about diaphragmatic spasm, we are told that it can also be detected by Litten's sign, an account of which may, it is said, be found in the "section on eponyms." This may indeed be so; we ourselves did not pursue the investigation further. It is common throughout the book to find a reference to signs or symptoms of which the explanation is given elsewhere. Even this confused arrangement of the material does not detract much from the value of a book which contains such useful information. Anatomie des lymphatiques de l'homme

By H. ROUVIÈRE, Professor of Anatomy in the Faculty of Medicine of Paris. Paris: Masson et Cie. 1932. Pp. 489. Fr.150.

THIS book represents the information of to-day concerning the lymphatic systems of man, set forth by a well-known authority. Prof. Rouvière has devoted years to this study, and to the collection of results obtained by other workers; the present work, therefore, has value for the clinician as well as for the anatomist. The subject does not lend itself to a description which communicates the author's enthusiasm to the reader, for it would be idle to pretend that continuous accounts of groups and subgroups of nodes with their attendant collector and drainage systems, do not in their repetitions become somewhat wearisome. Here at least one is fortified by the knowledge that one is receiving of the best. The brief descriptions in English text-books are in general agreement with the detailed statements made in this monograph, which also deals with variations not found in text-books. The recent work of Kiss and Botar on the relations between the lymphatic channels and the vegetative nerve-plexuses here noted is not well known in England. Of interest too is the division of the costal pleura *into areas; this division* was proposed some few years ago by Prof. Rouvière himself, and the separate drainage of the upper part was pointed out at that time. This part of the pleural sac is, embryologically, a secondary extension, and we may hope that the lymphatic system will be described some day from the standpoint of developmental morphology, to which it would seem in many ways to be adaptable. Prof. Rouvière's work should remain a standard for years to come, and provides a first-class book of reference with a complete bibliography.

RESEARCH ON MENTAL DISEASE

A SUPPLEMENT[1] to the eighteenth annual report of the Board of Control contains the record of scientific research at 60 different institutions under the auspices of the Board. The financial crisis most unfortunately caused postponement of a scheme of coördinated research which the Board hoped to be able to carry out under the sanction provided by Section 6 of the Mental Treatment Act. There is no branch of medicine, says the report, in which research is more needed, and to advance beyond the stage of early treatment to definite prophylaxis is impossible in the present state of knowledge. Even from the purely economic standpoint, a small reduction in the incidence of mental disorder would soon more than compensate for the cost of extended research. Meanwhile, however, much good scientific work continues to be done in individual hospitals; local successes are won here and there, but the Board sadly regrets the absence of any general advance. Nevertheless, it recognises a real progress in general efficiency; the process of hospitalisation continues steadily, and recent appointments to the post of superintendent have almost without exception gone to men of scientific outlook.

Communications regarding research have been received from 49 of the 98 county and borough mental hospitals, from 4 of the 13 registered hospitals, and from 7 institutions for mental defectives. This is an increase of 18 on the previous year. Summaries of routine laboratory work have been sent from 41 institutions, more than twice as many as last year. The Board looks forward to being able to collate these returns. Several of the mental hospital laboratories are recognised as county laboratories or undertake work for the public health authorities.

LABORATORIES

The modern treatment of mental disease, in particular the use of induced pyrexia, has added considerably to the pathological work which is necessary in an adequately equipped mental hospital. Most mental hospitals now have a laboratory of their own, and either a pathologist or one member of the staff specially interested in pathology. At Coney Hill (Gloucester) a pathological laboratory has been equipped for routine investigations and for some research, and here, as in several mental hospitals, the laboratory is proving useful to the city and county; the pathologist carries out tests for the medical officer of health and the Gloucester Royal Infirmary. Wassermann tests are being done on all the patients in the hospital, and in future the test will be made on admission. This measure, adopted in a number of hospitals, is giving interesting results.

Increasing attention is being given to chronic infective processes as a possible cause of mental disorder.

From Birmingham comes a study of "Nasopharyngeal Sepsis in 1001 cases of Mental Disorder," and several other papers on the same subject. The Board admits, however, that at this stage of the investigations there must almost inevitably be doubt as to the extent and frequency with which these conditions exert their influence, but hopes that every encouragement will be given to this line of study and treatment. There are also a considerable number of biochemical communications, including several studies in blood-sugar. Cardiff is investigating how far patients with a hyperglycæmic index vary in response to the administration of various internal secretions. An inquiry there into nitrogen metabolism suggests a cleavage between depressed patients on the one hand and cases of dementia præcox and stupor on the other. Much painstaking work on dysentery and allied infections has been carried out, and the report from Wakefield is a noteworthy lesson on the value of prophylactic inoculation. Caterham shows how much dislocation of administration and interference with patients' amusement *can be avoided by the employment of prophylactic methods*, such as Dick-testing and inoculation.

The Birmingham Research Board has concerned itself with the new stain for vessels in thick brain sections. A regular examination for localisation and type of vascular abnormality has been commenced, but unfortunately the financial position is causing delay. Among the conditions recognised are: microscopic areas of ischæmia, occlusion of vessels, scars of non-patent vessels, capillary leakages of serum, scars of old meningitis, patchy and diffuse loss of *cells, and periventricular atrophy*.

SPECIAL TREATMENT

Some 25 communications on general paralysis have been forwarded; malaria is being used at 72 institutions and various forms of sulphur in 20 more.

At Leicester of 88 cases treated since 1924 with malaria 27·3 per cent. have been discharged, and another 4·5 per cent have improved. Of the 43 deaths only 8 were associated with the treatment. Two of the discharged patients had been in the hospital on a voluntary basis. During last year eight men and one woman were infected by blood inoculation, and intensive courses of sulfarsenol, novarsenobillon, and bismuth were given after the malaria. Three of these patients were discharged as recovered and one was relieved. The blood from 150 new cases was tested by the Vernes method, and this test was compared with the Wassermann test. There was only one discrepancy: a known syphilitic in which Wassermann reaction was positive and the Vernes negative.

At Winwick only 12 of the 21 general paralytics admitted were in a sufficiently early stage for malarial therapy—a regrettable fact, doubly so because it seems to have been partly due to shortage of beds. An interesting report on the serological results and another on the Meinicke reaction are published from the same hospital. Induced pyrexia is being tried for several varieties of mental disorder; some hold that the fever has a specific effect, but the majority ascribe the results to psychological changes. In any case there is no doubt of the importance of using the interruption. in phantasy life to push occupational therapy. A number of studies of dementia præcox have been made; at Long Grove the effect of stimulation by carbon dioxide has been tried, and at Rainhill diathermy has been used. The histology of the digestive tract in these patients has been studied at Ewell and Colney Hatch and the endocrine function at Storthes Hall. Rainhill has concluded that there is no characteristic histopathology of the brain, and that the most constant feature is fibrosis of the solid viscera, with the kidney and spleen primarily involved.

Several hospitals have studied the ductless glands, but the Board feel that, on the whole, better value for time and labour could be obtained by studies based less exclusively on these organs. A number of clinical accounts of cases and of descriptions of special methods of treatment have also been received, and the Board wishes it had more reports on experimental psychology. Horton has presented a report on the application of psychology in the realm of psychiatry. Cardiff has studied the relationship between emotional tension, as shown by the psycho-galvanic index, and the hyperglycæmic index, and has shown a parallelism in psychotics, the variations in the hyperglycæmic index depending *not on the type of psychosis* but on the degree of emotional tension present. Prognosis, in the opinion of the Board, is worthy of more attention than it receives.

The Therapeutic value of BRANDY–

its lifting and sustaining powers—as compared with other spirits depends on the presence or absence of the higher Alcohols or Ethers. These in turn depend on Grape, Soil, Stills employed, Climate, Storage, Selection and Experience.

It is quite easy to make a spirit from grape wine—It is neither easy nor cheap to make a Brandy containing the qualities you want.

Cognac Brandy alone provides them.

Take no risks; ensure the results you expect

Prescribe Brandy distilled in Pot Stills from Wines grown in the best Cognac districts; Matured in warehouses which have been filled with Cognac Brandy for centuries; Made by Men with the inherited Experience of Seven Generations.

In short—Prescribe MARTELL'S BRANDY

and know *that you are doing the best possible for your patients.*

An Essential Factor in LONDON HOSPITAL CATGUT

Tetanus free at the source

London Hospital Catgut is made only from Lambs reared on Virgin British Soil, and subject to certified ante- and post-mortem examination.

Such care is exercised both as to the pasturing of the lambs when alive, and the immediate removal and sterilization of the intestines within 2 hours of death, that we claim for London Hospital Catgut that it is Tetanus Free at the source.

Leading Surgeons and Hospitals specify London Hospital Catgut for its absolute sterility, and its conformity with the conditions laid down by the Therapeutic Substances Regulations, 1931.

Specify

LONDON HOSPITAL CATGUT

obtainable from all leading Surgical Equipment Houses

Reminders and Suggestions

ACECOLINE

Pure stabilised Acetylcholine Hydrochloride for the treatment of Arteritis, Raynaud's Syndrome, Arterial Spasms, etc.

Boxes of 6 Ampoules in doses of 2, 5, 10 & 20 ctgs.

ADREPATINE

A combination of Pluriglandular and Vegetable Extracts with Stovaine for the treatment of External and Internal Hæmorrhoids.

Ointment: Tube with Canula—Suppositories: Box of 16.

BIVATOL

A Lipo-Soluble Bismuth which is practically equal in effect to the Arsphenamine Compounds in the treatment of Syphilis, Yaws, etc.

Boxes 12 Ampoules of 2 c.c.

EMGE (LUMIERE)

Pure Magnesium Hyposulphite for the treatment of Alimentary Anaphylaxis, Migraine, Urticaria and all Allergic Conditions.

Tablets: Packages of 40. Ampoules, 10 c.c., boxes of 3.

HYPOTENSYL

The active principles of Viscum (Gui) with Hepatic and Pancreatic Extracts for the treatment of conditions associated with High Blood Pressure.

Bottles of 50 Tablets.

MYCOLACTINE

A combination of Bile Extract, Yeast, and Lactic Ferments for the rational treatment of Alimentary Toxæmias, Intestinal Stasis and Constipation.

Bottles of 50, 500 and 1000 Tablets.

Literature and Samples on request from

THE ANGLO-FRENCH DRUG CO., Ltd.,
11 & 12, Guilford Street, LONDON, W.C.1.

LONDON: SATURDAY, OCTOBER 8, 1932

A SIMPLIFIED TANNIC-ACID TECHNIQUE

THE teaching that tannic-acid treatment for burns necessarily involves such elaborate armamentarium as a general anæsthetic, a spray, and a cradle, has led to a general impression that its use is likely to remain impracticable except in hospital; but its manifest advantages in preventing absorption of toxic products are sufficiently widely recognised to throw discredit on the traditional greasy applications which, while alleviating pain, do not prevent sepsis, promote healing, or diminish secondary shock. This unsatisfactory position is reflected in the lack of precision which now characterises many pronouncements on the first-aid and home treatment of burns. Such teaching must be crisp and dogmatic if it is to be remembered in an emergency, when any uncertainty may cause unnecessary suffering. The supply of a long list of alternative applications to carron oil may reflect creditable doubt whether the first-aider should any longer be encouraged to offer immediate relief irrespective of ultimate results, but is not conducive to the prompt action which is the essence of first-aid treatment. The advisory medical committee of the Industrial Welfare Society evidently recognise this, for they definitely advise householders to replace the bottle of carron oil by (*a*) a supply of dry picric-acid dressings for applying to small burns: (*b*) a bottle of picric-acid lotion for application when the skin is broken; (*c*) a solution of bicarbonate of soda (prepared by the chemist with distilled water) for cleansing a dirty wound before applying the picric dressing. A dessertspoonful of baking soda in a pint of warm water is offered as an alternative to (*c*).

In the forthcoming edition of the First Aid Manual of the British Red Cross Society a dressing with lint or linen soaked in 1 per cent. picric-acid solution is also given first place, but the discussion of other possible applications to "a slight burn of naked forearm and wrist when shock is negligible" is rather nebulous. Tannic acid is dismissed as too elaborate and difficult as a first-aid measure except in permanent first-aid posts. Simple dressing "as used for any wound" carries the rider that its removal is often painful. Carron oil is said to relieve pain but "does not keep the area free from germs." Other oily preparations are mentioned with the warning that the application of oil and grease is not desirable if other substances are at hand, "as the subsequent treatment is rendered more difficult and less satisfactory though they do relieve pain." Finally it is suggested that powders such as boric acid, flour, starch, or arrowroot, made into a paste with water, can be applied to the dressing. Should the burn be very painful or should it be necessary to search for materials for dressing, the reader is advised to put the injured part into a basin of warm water with a heaped dessertspoonful of sodium bicarbonate. Another hypothetical case of which the first-aid treatment is fully discussed is a severe burn of both thighs and knees. If the materials are at hand strips of dressing soaked in "one of the solutions previously recommended" are to be applied, but if no other dressing is available the instruction is to cut off part of the patient's shirt, wring it out in water, and put it over the burnt part to exclude the air. The object of the emphasis laid on "excluding the air" in instructions to the public in connexion with burns is presumably the diminution of pain. In this instance the advice seems unhappy, as the patient's shirt might well be contaminated with organisms from sweat or even fæces, and no more unsuitable dressing than a piece of such material soaked in water could well be imagined.

A technique of treating small burns with tannic acid that does not involve the heroic measures outlined by the originators of this method has been sought in many places. Dr. D. M. GLOVER,[1] who reports a series of over 300 cases, has used compresses of freshly made tannic-acid solution as a first-aid dressing, and has found it advantageous to dispense with the thorough scrubbing of the wound under a general anæsthetic. Mr. J. H. HUNT and Mr. P. G. SCOTT have gone a step further towards working out a technique suitable for routine domestic use. Their advice, described on another page, of reinforcing with collodion the crust which develops after the application of tannic acid, gives protection not only against mechanical damage but against infection at the edge; and the success which they have achieved, after gentle cleaning of the surrounding skin, with no more elaborate equipment than a camel-hair brush, a teaspoonful of tannic-acid powder in an ounce of water, and a moist gauze pad, should encourage the extensive trial of tannic acid in the home. Of the three methods they have used in the out-patient department of St. Bartholomew's Hospital, one, tannic acid in ether reinforced with gauze, is suitable for extensive and dirty burns, when oil or grease has been used as a first-aid dressing, or when more than 24 hours has elapsed since the accident. The second method, tannic acid in ether reinforced with gauze and collodion, results in an extra strong crust, and is advised in clean cases when an anæsthetic is needed on other grounds—e.g., in nervous patients and young children. Tannic acid in a watery solution reinforced with collodion on the third day will, it is believed by the authors, have a wide application; no anæsthetic is needed, little pain is felt, and the collodion seems to make the affected area less liable to become moist and soft under a dressing. This method is not put forward as definitive; it seems probable that modifications might be devised to avoid the necessity of removing gauze adherent to the crust. But it should serve to stimulate other attempts to adapt tannic acid treatment to first-aid conditions, and to relieve the patient's friends from the anxiety occasioned by the disrepute into which classical methods have fallen.

THE DIAGNOSIS OF EXTRA-UTERINE PREGNANCY

IN 1851 CHARLES D. MEIGS, of Philadelphia, wrote regarding ruptured tubal pregnancy, "Who is he astute enough to discriminate betwixt all the possible causes of such phenomena with so much clearness as to warrant him in the performance of a gastrotomy for Fallopian pregnancy?" The early recognition of ectopic pregnancy, even after rupture, remains to-day one of the most difficult diagnostic problems with which the gynæcologist is confronted. In a recent paper[1] OTTO VON FRANQUÉ, of Bonn, reminds us that though there may be significant warning signs there is often no missed menstrual period, since (according to his estimate) the ovum may be embedding for anything from 7 to 18 days before the next period falls due. When bleeding occurs it is, of course, liable to be mistaken for a period, though it is often too early, but it does not cease within the time limits of a period; while in a very early intra-uterine abortion the bleeding often does cease after a few days. During all this time the enlargement of the tube is so slight as not to be palpable even by an expert examiner. The Aschheim-Zondek test may thus be useful here, for in cases of pregnancy it is usually positive a few days after the first missed period, and at any rate it is positive at a time when by no other means could the fact of pregnancy be certainly established. Unfortunately the reaction becomes negative 8–12 days after death or expulsion of the ovum, or even after three days if there has been gradual interference with the placental circulation. The reaction is therefore of value only if it is positive. If death of the ovum has occurred the gynæcologist may elect to wait rather than to operate immediately; the gradual disappearance of the positive reaction may be observed, and operation may never be necessary unless absorption is unduly slow or bleeding protracted.

FRANQUÉ believes that diagnosis of unruptured and undisturbed tubal pregnancy is possible only in isolated cases. The differential diagnosis between a tubal pregnancy and an ovum growing only in one half of a normal uterus may be confusing, but the latter condition is happily rare. A retroflexed uterus may be taken for a hæmatocele in Douglas's pouch. The indefinite boundary of a hæmatocele, its immobility, its tenderness, and the relation of the uterosacral ligaments as felt per rectum should enable the distinction to be made, especially if the examination be carried out under anæsthesia. HÖHNE, he says, has reported a case in which a still intact tubal pregnancy was diagnosed by a decidual cast of the uterus. This is usually passed only after death of the fœtus, but it may be the first cause of bleeding, and he emphasises the importance of examining carefully everything discharged from the uterus when tubal pregnancy is suspected. He states that there is always pain on the side of the pregnant tube; if the pain is right-sided appendicitis may be its cause, but since in either case laparotomy is indicated this is of little moment; a median incision should be made to allow complete exploration of the pelvis. In appendicitis the pain and swelling tend to be higher up; the leucocyte count tends to be increased; and the red blood corpuscle sedimentation rate accelerated. In uninfected ectopic both are likely to be normal. The early signs of pregnancy and the vaginal bleeding too are helpful, though it is important to note that the latter may be very slight and visible only on vaginal examination, or even through a speculum. Occasionally appendicitis and tubal pregnancy may coexist, and there may be a causal relationship between them. In diagnosis between appendicitis and inflammatory tubes on the one hand and extra-uterine pregnancy on the other, pulse and temperature are of little use, as both may be little raised or even quite normal; but a high temperature excludes a simple non-infected ectopic, whereas complete pulse loss can occur without any internal bleeding in perforating peritonitis.

When a catastrophic rupture of a pregnant tube has occurred the signs are usually characteristic: peritoneal shock, abdominal pain and meteorism, small and rapid pulse, air-hunger, faintness, and pallor. Shoulder pain may be present, but may also occur in appendicitis and cholelithiasis. There is usually dullness in the flanks, but fluctuation is absent on account of the coagulation of the effused blood. If a woman in previously good health is suddenly seized with severe abdominal pain accompanied by meteorism, loss of pulse, pallor, coldness of the extremities, giddiness, and faintness the surgeon's first thought should be ruptured ectopic; no time should be lost in attempts at differential diagnosis but immediate laparotomy carried out. Although ruptured ectopic is the most likely finding the lesion may be a perforating peritonitis of any kind, torsion of an ovarian tumour or of a myoma, or one of the rarer causes of intraperitoneal hæmorrhage. A case has been recorded in which the doctor mistook the ruptured ectopic for acute poisoning and applied the stomach pump. As to treatment, FRANQUÉ holds that if the patient is not acutely ill expectant measures may be adopted at least for a time—bed, ice-bag to the abdomen, and possibly ichthyol and glycerin tampons to the vaginal vault. Should the swelling increase or the patient's condition deteriorate, operation must be immediately undertaken. He condemns the use of protein shock therapy to hasten absorption and also exploratory puncture, whether through the vaginal vault or abdominal wall. This measure should never be adopted by the practitioner, and only exceptionally in hospital, and never without all preparations made for immediate operation.

---

[1] Medizin. Klinik, 1932, xxviii., 989.

In this connexion it is interesting to note that KURT KAISER,[2] while not condemning exploratory puncture so wholeheartedly as FRANQUÉ, also emphasises that it must be done with all aseptic care, and only as a preliminary to immediate operation. If blood is aspirated laparotomy must be performed, though the aspiration of blood is no certain indication of a ruptured ectopic. In one of his cases the blood was obtained from a tube into which hæmorrhage had occurred because of a twisted pedicle.

THE MOUTH-BREATHER

NASAL obstruction is generally regarded as an important factor in the production of deformities of the palate, dental arches, jaws, and face. But there are some who dispute this view, and their arguments were ably presented by Mr. WARWICK JAMES and Mr. SOMERVILLE HASTINGS, in opening a discussion at the Royal Society of Medicine.[3] They emphasise the well-known tenacity with which young children cling to breathing through the nose in spite of difficulties; as it is easier to draw a deep breath through the open mouth than through the nose, the urge to nasal respiration is probably physiological, and they hazard the suggestion that variations of species, acquiring the easier habit of mouth-breathing, may have been wiped out by intercurrent disease, having lost the valuable function of the nose in protecting the individual from throat and lung affections. As an instance of the powerful urge to nasal breathing, they quote the case reported by C. W. RICHARDSON of an infant born with bilateral occlusion of the posterior nares, who was only kept alive by relays of assistants holding the lips apart until, by the end of the second week, the baby had learnt to breathe through the mouth; RICHARDSON, indeed, suggests that some infants, who never breathe and are stillborn, are instances of this deformity. Patients who have complete nasal obstruction from this cause have, in the majority of cases, high-arched palates, but they seldom suffer from deformities of the face or nose, nor, it may be added, from chest deformity or catarrhal diseases of the ears; they take perforce entirely to mouth-breathing, and escape the changes which result from respiration through a partially obstructed passage, or from infection, or from both these causes. On the other hand, marked changes in the nose and face are not infrequently associated with partial nasal obstruction. The theory that these are due to disuse of the nose during growth is negatived by their absence in complete congenital obstruction. A second theory suggests that, during normal respiration, there is a rhythmic increase and decrease of air-pressure in the nose, which acts as a stimulus and is absent in nasal obstruction; but this also is absent in complete congenital occlusion.

Mr. JAMES and Mr. HASTINGS hold that deformities of the nose and face are the cause of nasal obstruction rather than caused by it; but their failure to provide a satisfactory explanation was not regarded by Mr. E. B. DOWSETT, who presided over the section, as adequate reason to invert the usual arrangement of cause and effect; the relationship of obstruction to these deformities still remains obscure. Mr. JAMES and Mr. HASTINGS believe that the deformities are caused, not primarily by nasal obstruction, but by failure to close the mouth, either anteriorly or posteriorly, at what they term the two sphincters of the cavity. This they consider due most commonly to failure of muscular control; as corroboration, they found a history of severe illness or operation in infancy in half of the 52 cases examined. Of other causes, conditions demanding a rapid respiratory exchange, such as pneumonia, may initiate a habit of keeping the mouth open, as also may imitation of other members of the family, or a faulty position of the head. It must be admitted, however, that these considerations are not very convincing. Their description of the manner in which the palate and jaws are moulded by forces acting on them when the mouth is closed follows more usual lines and, in their opinion, the most important factor is the negative pressure produced within the closed mouth and maintained by the action of the tongue. Contrary to general opinion, they hold that nasal obstruction is rarely caused by adenoids, and support this view by the statement that most of the children who are diagnosed to have adenoids and benefited by operation have a mass of lymphoid tissue in the nasopharynx of such a size that it would not cause obstruction. They seem to have overlooked the probability that a small non-obstructive mass, when infected, may produce swelling of the adjacent nasal mucous membrane, and thus become an effective cause of obstruction.

SUNSHINE IN HOSPITALS

THE Royal Institute of British Architects recently appointed a Joint Committee on the Orientation of Buildings, and its report has now been published in the *Journal* of the Institute. The committee, the chairman of which was Mr. P. J. WALDRAM, F.S.I., in addition to architects, included representatives of the Board of Education, the Ministry of Health, the Building Research Station, and Sir LEONARD HILL, formerly director of the department of applied physiology at the National Institute for Medical Research. In the section of the report dealing with hospitals regret is expressed that the medical profession "has failed to bring sufficient pressure upon hospital authorities and hospital architects to secure the provision of solaria in which sunshine on the beds of patients can be used as a curative rather than as a restorative agency." Hospital planning, it is added, "has, with few exceptions, become standardised, not to say crystallized, or even fossilised, into the familiar ward with its long axis running north and south with windows on each side facing east and west between beds placed at right angles to the external window walls. Hospital wards are still planned with over 60 per cent. of the external wall space taken up by solid brick-work and the windows so spaced that the patients receive the minimum of sunshine."

---

[2] Ibid., 1932, xxviii., 1057.

[3] Section of Odontology, to which members of the Section of Laryngology were specially invited. See THE LANCET, 1932, i., 936. The opening paper appears at length in the Jour. Laryng. Otol., September, 1932, p. 614.

With this arrangement the committee contrast one that has been adopted in Copenhagen whereby hospital beds are placed parallel to the wall in groups of four. This has, they say, a further psychological value in that, instead of lying in a long ward and seeing all day and every day a large number of comparative strangers in a state of ill-health, the patient is in a small group of four or six with whom he can feel at home so far as his illness may allow. The report omits to mention how, largely on the initiative of Mr. L. G. PEARSON, F.R.I.B.A., this lengthways arrangement of beds has been creeping into new hospital designs in this country, where a further development has been the erection of wards with a few piers along the walls and long sliding windows which fold together. In suitable weather the whole sides of the wards can be opened up, allowing for the free and full ingress of sunshine and air. The actual amount of solid wall mass is thus only 8 per cent. of the wall surface, instead of 63 per cent. as in the older type of wards. After careful investigation the additional cost of maintaining the necessary minimum temperature in view of the larger window space is found to be immaterial, and supervision is not interfered with. A material advantage of this type of "veranda" ward is the elimination of balconies in many-storied hospitals, which both shade and obstruct the windows of lower floors. It is, however, pointed out that the maximum admission of sunshine must be considered in due relation to other considerations material to the efficiency of a hospital as a whole, remembering always that in certain mental cases and in hospitals for the treatment of advanced cases of pulmonary tuberculosis exposure to direct sunshine may be undesirable.

The committee insist that it is essential in the design of hospital wards that architects should confer freely with the medical staff and ascertain the number of beds or wards which should be designed for cases where full insolation is undesirable. Clear and simple methods of predetermining generally and of testing in detail the insolation of wards and other units should be invaluable to architects engaged in hospital planning. The committee conclude that the proper orientation of hospitals may be considered as governed by the following general factors: (1) the type of disease which it is desired to treat; (2) the best type of ward to meet (1); (3) the best spacing between ward and other buildings; (4) the desirability of choosing sites and lay-outs which will secure proper orientation for all the various units.

ANNOTATIONS

THE PLIGHT OF TYPOGRAPHY

THE announcement made last week by *The Times*, that it was about to embody the results of two years' research and reorganisation in a new type especially designed for its own use, serves to emphasise the difficulties which beset, and which have hitherto almost prevented, all scientific progress in the underlying problems of typography. To the manifold scientific difficulties inherent in typography have been added others, not only practical and economic, but arising from the prejudices of numerous printing "experts" who have been accustomed only to the historical, artistic, and literary approach. The difficulties were examined, and the complexities of the problem of legibility were comprehensively set out, for the first time in the report on "The Legibility of Print," published by the Medical Research Council in 1926.[1] The author, Mr. R. L. Pyke, concluded that only the grossest typographical differences affected legibility, strictly so-called; and that habit, æsthetic, and associative considerations accounted for the greater part of a reader's reaction to a type-face. These conclusions appear to support, not the traditional, "artistic" printer, with his purely personal reactions, on which he too often and quite illogically dogmatises, but the need for further experiment and scientific study. The new type of *The Times* is not, it must be admitted, especially pleasing at first glance; but this proves nothing. Every psychological experimenter knows how quickly laboratory habits can be formed by subjects and how unreliable as a permanent index are introspective reports upon first reactions to a new stimulus. In so far as any evidence worthy of the name can be invoked, it goes to show that type such as that introduced by *The Times* is desirable. We say desirable of set purpose, for it may prove that the concept of "legibility" will have to be discarded, and that it will become impossible to say more of a type or publication than that it possesses in definite measurable degree this or that characteristic. For instance, the degree of contrast between "thicks" and "thins," the length of line, and the texture (not colour) of the paper, are problems which seem likely to yield fairly reliable answers to scientific experiment long before the compound problem of legibility itself. For, unlike legibility, each of these factors can be conclusively defined, and can be shown, if varied, to increase or decrease some relevant reaction in the reader; thus contrast affects speed in reading and also the tendency to confuse similar letters; length of line may be responsible for hesitancy in reading due to focus alterations and fatigue in eye movements; while glossiness of paper influences rapidity and fatigue in fixation and accommodation. Glossy paper, whatever its virtues, makes print invisible at points; it increases glare, and by acting like a mirror it disturbs the accommodation of the eye.

Legibility, as understood by the ordinary reader—indeed the very appearance of a type-face—can be as much affected by accidental factors that do not even arise in the theoretical or æsthetic problems of design, as by intentional variations in the character or size of the type-face itself. It is easy to convince an ordinary person that he is reading different types when two pages are set in the same type, but one is over-inked, the other under-inked, one is on soft fluffy paper, the other on hard glossy paper. Indeed, there may actually be a greater difference in such a case than where the two types chosen are actually different.

---

[1] The Legibility of Print. By Richard L. Pyke, M.A. Med. Research Council, Spec. Rep. Series No. 110. London, 1926.

It is not surprising if the influence of legibility cannot be isolated or measured. Refinements in design and a classical pedigree contribute less to typographical progress than an experimental attitude, freedom from affectation, and a high standard of production among those actually engaged in the printing industry.

VENOCLYSIS FOR ALIMENTARY TOXICOSIS

DIARRHŒA and vomiting in the infant, whatever may be their original cause, produce a clinical picture which has been well described as "alimentary toxicosis"; it is accompanied by dehydration, impaired circulation, and in many cases by a true acidosis. The method of treatment recommended by Karelitz and Schick at the last session of the American Medical Association[1] is based on the assumptions: (1) That the diarrhœa and vomiting, when once established, are symptoms of a non-specific hypersensitivity of the gastro-intestinal tract; even water given by mouth may act as an irritant and increase the diarrhœa and vomiting. (2) That dehydration is a secondary symptom and the diseased cell is unable to retain either water or salts; the suppression of urine which tends to follow the excessive loss of fluid by the bowel results in turn in an accumulation of katabolic products in the blood. (3) That the toxic symptoms of the disease are therefore at least aggravated by dehydration; the rationale of prolonged administration of fluid by the intravenous route is thus to rest the gastro-intestinal tract and to combat dehydration as effectively as possible. To infants exhibiting the picture of toxicosis these authors accordingly give as a routine a 5 per cent. solution of dextrose in normal saline intravenously, 100–200 c.cm. rapidly in 15 to 20 minutes, the flow being then reduced to 15–40 c.cm. per hour (5–10 drops a minute). The total daily amount of fluid given was about 60 c.cm. per lb. of body-weight, and in addition 75–150 c.cm. citrated blood was transfused as soon as possible after the venoclysis was started, 1–2 c.cm. of epinephrine (1 in 1000) being added to 250 c.cm. of the dextrose solution in order to improve the circulation. For the first 12 hours of treatment no fluid is given by the mouth except enough to moisten the mouth and pharynx, after which 10–20 c.cm. of water is offered every two hours. A two-to-one mixture of milk and water with 5 per cent. added dextrose is allowed when detoxication seems complete, and in no case before the end of 36 hours. Starting with 5–10 c.cm. of the mixture two-hourly, the amount is increased by 5–10 c.cm. at each feed for the next three or four days, a similar addition being then made every two or three days. The venoclysis is discontinued only after all signs of toxicosis have disappeared, and the whole routine is repeated if symptoms recur. The authors emphasise the importance of reducing examination and manipulation of the patient to a minimum; body temperature is measured in the axilla in preference to the rectum. The technique of prolonged venoclysis necessitates fastening the arm or leg used to a padded splint which in turn is fastened to the bed. After the vein has been exposed under local anæsthesia, a Lindeman (No. 18 or 19) cannula is introduced and tied in with catgut ligatures. The fluid is given from a gravity outfit with rectal drip bulb and a thumbscrew clamp. The period of venoclysis varied from 9 to 150 consecutive hours—usually from 36 to 72—and in only about one-third of the cases was a second insertion of the cannula necessary on account of clogging.

Whilst the technical difficulties of such a method of treatment may limit its applicability, the results obtained by Karelitz and Schick are extremely encouraging. In the last two and a half years only 6 of 53 cases so treated died—a mortality of 12 per cent. to be compared with an average mortality of 64 per cent. for the preceding ten years at the same hospital.

THE HISTORY OF THE C.D. ACTS[1]

THE history of the Contagious Diseases Acts is well outlined in a short life of that humane reformer, James Stansfield, which has just been written by the authors of the valuable pieces of social history entitled the "Town Labourer" and the "Village Labourer." Stansfield, whose memory is universally respected as a Victorian champion of sex equality, made his mark in the House of Commons immediately upon his election in 1859, obtained office three years later, lived down a furious agitation against him for his generous but indiscreet relations with Mazzini, and in 1871 obtained Cabinet rank, under Gladstone, as President of the Poor-law Board. Local government was at this period a subject of anxious consideration among the forward thinking, of whom Stansfield was a leader, and during his work for the reform of the poor-law, where he displayed his views on sex equality, he became intensely interested in the working of the Contagious Diseases Acts. These Acts came into force in 1864, with the well-meant intention to check the ravages of venereal disease among soldiers and sailors on the continental plan of *maisons tolerées*. The working of the Acts was soon seen to be open to abuse, and to be attended with gross persecution of a particularly helpless class; none the less the public value of the Acts was insisted upon by the majority of the public, and those who made the attempt to obtain their repeal found their task an extremely difficult one, and their words and actions subjected to persistent misrepresentation. The bitterness of the struggle was maintained by tactlessness and exaggeration on both sides, and it was 12 years before James Stansfield and Josephine Butler saw the cause which they led with such devotion finally triumph. This short book records a noble piece of social work, and Stansfield emerges from its pages as a brave and good man, able to discharge practical work without any faltering with his conscience.

GLYCÆMIA IN HEALTH AND DISEASE

MANY observations have been made on the behaviour of the blood-sugar in fasting healthy individuals and on the shape of the curve obtained by charting estimations of glucose tolerance in healthy persons and those suffering from various disorders. But these observations are widely scattered through medical literature and they have often been made upon relatively small groups of subjects suffering from a particular type of disorder. Dr. Birger Enocksson, working at the Serafimer Hospital in Stockholm, has done a useful piece of work in making an extended series of similar observations.[2] The investigation included a study of the fasting blood-sugar levels over long periods in health, which he found to be remarkably constant, and of the alterations brought about both in health and disease by the ingestion of a gramme of glucose per kilo of body-weight, and by the injection of 1 mg. of adrenaline. His observations help to bring into proper perspective a large number of facts already known. Their principal interest, however, lies in the demonstration of the relationship between the glycæmia produced by the ingestion of glucose and that produced by the injection of adrenaline. In the healthy subject Dr. Enocksson found that the injection of adrenaline produced a far greater and more enduring glycæmia than that brought about by the ingestion of glucose; on plotting curves of the response in the usual manner that for adrenaline rises above and extends beyond that for oral glucose; this space he calls the "positive adrenaline area." In many morbid conditions, all having the common factor of cachexia or toxæmia, it was found that some degree of hyperglycæmia existed even in the fasting subject; in gastric carcinoma in particular, the fasting blood-sugar was often found at a level which, on the face of it, would have justified a diagnosis of diabetes, and the glucose-tolerance curve was higher and longer though never showing the typical plateau of diabetes. That this hyperglycæmia was not very characteristic of malignancy was shown by the finding of a very similar state of affairs in simple peptic ulcers and in a variety of other conditions, infective and non-infective alike, but all having the common factor of toxæmia or cachexia. The hyperglycæmia in all these morbid conditions differed from that of healthy individuals in that the blood-sugar was raised to a higher level by oral glucose than by adrenaline; that is to say, in contradistinction to the state of affairs in the normal subject the "adrenaline area" was negative—a fact which appears hitherto to have escaped recognition. It may not prove of much diagnostic value, but it serves to draw attention to the effect of adrenaline in altering the glycæmic response in conditions associated with toxæmia or cachexia, and to the danger of attaching importance to such alterations apart from their value as evidence of toxæmia.

B C G VACCINATION OF PIRQUET-NEGATIVE NURSES

THE Pirquet-negative probationers of the Ullevaal communal hospital in Oslo, whom Dr. J. Heimbeck has been inoculating with B C G since the beginning of 1924, are becoming objects of world-wide interest. In the period Jan. 1st, 1924–August 1st, 1931, 454 probationers were found[1] to be Pirquet-positive and were therefore not inoculated. Twelve of them (2·6 per cent.) subsequently developed signs of active tuberculosis. In the same period there were 253 probationers who, though found to be Pirquet-negative, were not inoculated with B C G. Among them there were 75 (29·6 per cent.) who subsequently developed signs of active pulmonary tuberculosis. A third group of 207 probationers in the same period were found to be Pirquet-negative and were inoculated with B C G. Twenty-one of them (9·6 per cent.) subsequently developed signs of active tuberculosis. The subcutaneous injections of B C G did not have a uniform action. Even on one and the same day, with the same dose and the same solution, the persons inoculated reacted differently; and while during certain periods the B C G was potent, it seemed to be partially or wholly inert at other periods. A striking difference was observed between the subsequent tuberculosis morbidity of those probationers who became allergic and Pirquet-positive after inoculation, and of those who did not. Among the 88 in the first category there was only 1 who subsequently developed signs of active tuberculosis, whereas there were 16 cases of tuberculosis developing among the 60 not rendered Pirquet-positive by the B C G. It should be noted that there were 4 other cases of active tuberculosis developing among the 43 probationers who were not included in this calculation for lack of adequate observation or the 16 in whom the Pirquet reaction was doubtful. As it may be assumed that all these probationers were exposed to the same risk in the course of their duties, Heimbeck is inclined to conclude that (1) the allergic properties and local action of B C G are variable, and (2) only those probationers who become allergic in response to inoculation develop immunity to tuberculosis.

SHORTNESS OF BREATH

THE search for some objective explanation of the feelings associated with shortness of breath has long been unsuccessful. In a recent paper[1] Prof. O. Bruns and Dr. R. Herbst arrive at some interesting conclusions from their study of the alterations in the functions of the lungs in certain chronic pulmonary disorders. They first investigated, with a recording spirometer, the lung volumes, volume of respiration per minute, oxygen consumption, and the respiratory rhythm of a series of patients falling into three groups, according as they were afflicted with emphysema, with asthma, and with bronchitis. Their findings confirm those of previous workers, since they observed increased residual air and increased minute volume in emphysema, and reduced vital capacity in asthma, with increased frequency of respiration even at rest, so that with a low tidal air the minute volume of respiration is brought up to or even above normal. A prolongation of the time of expiration they found to be common to all these conditions and indeed almost always to accompany dyspnœa. Similar spirographic measurements were carried out while light work was being performed. Minute volumes rose just as in normal subjects, but the oxygen intake in unit time was less than in normal controls with the same amount of work and a greater oxygen debt occurred. The investigation of these patients in detail, however, presented many difficulties, including the satisfactory elimination of psychical factors. An attempt was therefore made to imitate the mechanical disadvantages under which patients with emphysema and asthma suffer. For the former group healthy subjects wore a broad band round the chest fixed in the extreme expiratory position; to imitate the difficulty experienced in asthma narrowing of the air-passages in the apparatus was arranged to hinder expiration. These models gave the same type of readings on spirographic investigation as their originals. A further experiment showed that on heavy work such subjects broke down much earlier from dyspnœa than normal controls, although the oxygen deficit was not unduly high, and the authors conclude that a reduction in oxygen intake is not the cause of such dyspnœa. Following their observations on the prolonged expiration time found in all their experiments with patients and models they set about disciplining the breathing during work. The subjects were encouraged to breathe in and out slowly and deeply and although the ventilation and the oxygen intake were actually less than with the natural uncontrolled breathing the breakdown at work came considerably later. The authors therefore concluded that the dyspnœa in chronic pulmonary disease was probably not due to any interference with ventilation or with gaseous exchange in the lungs, but was intimately connected with the prolongation of expiration. This led to a consideration of what effect such alteration in respiratory rhythm could have upon the circulation, and the conclusion is reached that prolongation of the expiratory phase will interfere with the venous return to the right side of the heart and hence cause congestion in the tissues. This in turn will produce some alteration in the hydrogen-on concentration of the blood around the cells of the respiratory centre, a conclusion already reached by Prof. F. R. Fraser[2] from a study of the blood gases. ncreased respiratory effort follows the stimulus f such a change in an individual already experiencing ome resistance to normal respiration. The greater uch resistance, the longer the expiration time and he greater the change in the centre. In this vicious ircle lies the cause for the subjective feeling of dyspnœa. Prof. Bruns and Dr. Herbst believe that by disciplining the breathing so as to equalise the inspiration and expiration time the vicious circle can be broken and dyspnœa relieved. On this basis various empirical systems of breathing exercises have already been devised.

LUMBAR PUNCTURE IN NEUROSYPHILIS

At the Fournier centenary congress held in Paris ast May the problem of neurosyphilis was discussed, and a resolution was unanimously passed expressing the opinion of the congress that lumbar puncture was the best method of investigating the state of the nervous system in the earlier stages of syphilis, and that every syphilitic should have his cerebro-spinal fluid examined at some definite time after his infection. In a recent paper Ravaut[3] has given his opinion that the time at which one can learn most from this examination if, as is usually the case, it is only practicable to do one lumbar puncture, is the end of the third year. This opinion is based on 30 years' experience of lumbar puncture in the early stages of syphilis.

The abnormalities in the cerebro-spinal fluid may concern the cell count or the protein only, or these may be combined with positive Wassermann and colloidal reactions, forming what Ravaut calls a "complete reaction." The latter he considers as indicative of meningo-parenchymatous lesions, the intensity of which may be judged from the nature of the cerebro-spinal fluid changes. When the cell count only is increased, it is probable that only the meningo-vascular system is attacked, whereas an excess of protein (which is usually associated with positive colloidal reactions) is evidence rather of a parenchymatous lesion. His experience has confirmed what is now generally recognised—namely, that an increase in cell count and protein is commonly found during the early months of syphilis, but that the majority of these reactions disappear either spontaneously or under treatment without being accompanied by any clinical neurological sign. The minority are more intense and persistent, and these may be divided into two main groups :—

(1) Those in which no clinical symptoms make their appearance, but which persist for months or years. In such cases post-mortem examination may show evidence of old-standing lesions of the nervous system. Occasionally a slight clinical sign, quite disproportionate to the pathological lesion, makes its appearance in such cases.

(2) Those in which the cerebro-spinal fluid reactions increase progressively and persist, and in which, after a latent period of varying duration, the clinical signs of a severe neurological disease make their appearance. To this type Ravaut gives the name "pre-clinical."

It is on these two types of reaction that attention should be chiefly focused, as they provide definite evidence of involvement of the nervous system. And, as the great majority of the more ephemeral reactions have disappeared by the end of the third year, it follows that a lumbar puncture performed at this time is more likely to give trustworthy information than one which is performed at an earlier period.

Ravaut has also produced evidence to show that neurosyphilis becomes progressively less latent, that is, less confined to changes in the cerebro-spinal fluid, the further from the time of infection the case is followed. Of the patients in whom cerebro-spinal fluid abnormalities were found at any period, only 5 per cent. of those examined during the secondary stage showed any clinical evidence of neurosyphilis, whereas from the end of the third year onwards the proportion gradually rose so that between the seventh and eighth years half showed clinical signs, and at the tenth year only one-fifth remained of a latent form. He considers therefore that an examination of the cerebro-spinal fluid becomes progressively less imperative after the end of the third year from the date of infection, although it may still be necessary when any neurological sign, however trivial, makes its appearance.

ACCIDENTS FROM DISINFESTATION WITH HYDROGEN CYANIDE

Although the destruction of rats and insect pests by fumigation with hydrogen cyanide is now widely practised on sea-going vessels, this fumigant has been little used in dwelling-houses, at least in this country. For certain purposes, as for instance the destruction of mites in furniture, it is the only sure method, and it has many advantages in the eradication of parasitic insects; but obviously the risk to human life is great and the fumigation should be carried out with meticulous precautions. Dr. F. M. Messerli,[1] has recently drawn attention to two deaths which occurred in Lausanne following upon fumigation with hydrogen cyanide for the destruction of bugs. In one case the operators had apparently taken no precautions to ensure that access to the fumigated flat was prevented during the preliminary period of airing, prior to thorough ventilation; in the other, the gas, which is highly diffusible, found its way through cracks in floors and ceilings to a lower flat and caused the death of one of the occupants. Messerli draws attention to the risk of retention of the gas in water, moisture, bedding, cushions, hangings, and foodstuffs, and he lays special emphasis upon the impossibility of limiting the field of action of the fumigant in tenement buildings, although this can apparently be done on ships. He cites ten instances of poisoning in Paris, reported by Kohn-Abrest, and advocates universal prohibition of hydrogen cyanide. In his opinion sulphur dioxide is sufficiently lethal to pests, and is far preferable in view of the lesser risk to human life. In this connexion we may note that sanitarians in British ports have not ceased to rely upon sulphur for the fumigation of ships, and that in other countries, where sulphur dioxide had fallen into disrepute, a more favourable opinion of its efficacy is gaining ground. The point still to be settled is the reliability of sulphur dioxide as a destroyer of the eggs of parasitic insects, a subject which was touched upon at a meeting of the Royal Sanitary Institute[2] some years ago, and is being investigated afresh by Dr. W. C. Gunn at Glasgow. The question deserves further consideration in this country because the danger to life from the indiscriminate use of hydrogen cyanide is far from negligible.

LEEDS THEN AND NOW

IN 1836, when the Municipal Corporations Act of the previous year came into force, the members of the Leeds town council, elected for the first time by popular vote, were mostly men with no experience of municipal administration. In an earnest endeavour to learn what tasks lay before them—and possibly appalled by the condition of the town—they did a very sensible thing and appointed a committee to make a survey. This report, which appeared in the *Journal* of the Royal Statistical Society, has now been reprinted with a foreword by Mr. Councillor Hawkyard, chairman of the mental health services committee and Lord Mayor in 1930–31. As a picture of town life early last century, with its commencement of the industrial era, and its rapid multiplying of the population, it makes interesting reading, and shows what enormous progress has been made in a relatively short space of time. Populous districts of the town were wholly without sewers; in rows of houses the cellar dwellings (of which there were over 500) were seldom dry; the conditions of the streets were indescribable, many of them being recorded as—

> "Deficient in sewerage, unpaved, full of holes, with deep channels formed by the rain intersecting the roads and annoying the passengers; some ill-lighted, and some without lamps; with cellars sometimes so dangerously exposed that passengers are liable to frequent accidents; and sometimes rendered untenable by the overflowing of sewers and other more offensive drains; with ash-holes, &c., exposed to public view, and never emptied, or being wholly wanting, as is frequently the case, the refuse is accumulated in cellars, thrown into the streets, or piled against the walls."

In addition, nearly one-half of them were weekly so full of lines and linen as to be impassable for horses and carriages, and almost for foot-passengers. Public conveniences are "uncleansed because it is nobody's business," and as "everybody's perquisite, they become offensive in the highest degree." It is a picture which some modern critics of bureaucratic control might well pause to consider. Overcrowding was rampant; instances are given of five to six persons in each bed—"and there are generally two or three." One conclusion was certain, "that the greater part of the town is in a most filthy condition, which demands an immediate remedy."

Actually very little was carried out for many years. The council made application to Parliament for powers, the Leeds Improvement Act of 1842 being the result, but, Mr. Hawkyard concludes, "the council evidently became alarmed at the cost of the proposal, for very little was done by way of improvement until the council appointed a medical officer of health in 1866." Crime, religious accommodation, education, physical condition, occupational mortality, and the differential birth-rate all came under the eye of this committee. Their statistics of the size of family are of some interest. In 1925 the medical officer of health for Leeds drew attention in his annual report to the "disquieting significance" of the falling birth-rate, the fall, as is well known, not being equally distributed over all sections of the community. "It is from the poor that the population to an ever-increasing extent is deriving its recruits," he writes, "which means that the average fitness of the individual units is slowly but surely declining." Nearly a hundred years before his predecessors concluded that "thus it is evinced that the greatest proportion of births takes place among the lowest class; next among those employed in outdoor handicraft; then among indoor handicraftsmen; then among tradesmen; and lastly among independent and professional people." And this was before the popularisation of methods of contraception at whose door the differential birth-rate is so often entirely laid.

Leeds is not to-day without its particular and urgent problems, as perusal of its annual reports, and especially of such sections as that on smoke abatement will show. But in a little under one hundred years it has, in common with all England and Wales, travelled a long way in the endeavour to supply the amenities of life and the health essential to their enjoyment.

AN INDEX OF TOXIC DEGENERATION IN POLYMORPHS

THAT in states of toxæmia the cytoplasm of the polymorphonuclear cells undergoes more or less characteristic changes has long been recognised; they were carefully studied by Turck, and a description of them may be found in his "Vorlesungen über klinische Hæmatologie" (1912). The changes consist mostly in irregularity of the cell outline, increase in size and in basophilic tendency on the part of the cytoplasmic granules, and vacuolation. Various attempts have been made to assess the value of these changes in following the course of infective conditions, and lately M. S. Kugel and Dr. N. Rosenthal,[1] working at the Mount Sinai Hospital, New York, have investigated the use of the Schilling "hæmogram" and combined with observations on the degree of this toxic change. To secure a numerical expression of the amount of change they made use of the "degenerative index," obtained by dividing the number of polymorphs showing toxic change by the total number of these cells counted; the more severe the infection and the greater the degree of toxæmia the higher the index should be. For the identification of the toxic changes they found Jenner-Giemsa stain the most suitable. They regard the degenerative index as useful in itself, but its greatest value, they believe, is as a supplement to the hæmogram. The latter gives information as to the degree of maturity of the polymorphs and is some index to the urgency of the call upon the bone-marrow for their production. It gives, however, no information as to the nature of the call; a "shift to the left" may be produced either by an acute infection or by hæmorrhage. Such information is supplied by the degenerative index.

THE Murphy Oration of the American College of Surgeons will this year be delivered by Sir William Wheeler, past president of the Royal College of Surgeons in Ireland. The annual clinical congress at which it will be given opens at St. Louis on Oct. 17th. On leaving Dublin last week Sir William received presentations from Mercers Hospital and the Ministry of Pensions' Hospital, and from the City of Dublin Nursing Institution, of which he is chairman.

Dr. G. C. Anderson, deputy medical secretary of the British Medical Association since 1919, has succeeded to the post of medical secretary upon the retirement of Dr. Alfred Cox. Before joining the central staff of the Association, Dr. Anderson had considerable experience in general practice in Fifeshire, and was medical superintendent of the Wemyss Memorial Hospital. As a student of the University of Edinburgh he distinguished himself in several branches of athletics, and held the Scottish long-jump and hurdles championships. During the late war he was surgeon specialist to the 69th General Hospital in Egypt and in Palestine.

OPENING OF THE MEDICAL SCHOOLS

THE winter session opened last week with inaugural addresses at several of the London medical schools. Below we publish extracts from three of them. Dr. le Fleming spoke at St. George's, Prof. Halliday at Charing Cross, and Dr. McAlpine at the Middlesex Hospital.

THE GENERAL PRACTITIONER

BY E. KAYE LE FLEMING, M.B.
CHAIRMAN OF THE REPRESENTATIVE BODY, BRITISH MEDICAL ASSOCIATION

SOME day and somehow the health services of the country must be bound together in such a manner that every citizen of the State can obtain a full medical service in his home, or in an institution, where every resource of medical science will be at his service at a cost within his individual means. There is evidence enough that such provision can only be secured by some form of insurance, but the ultimate success of any such health machinery must depend on maintaining unimpaired the intimate personal relationship between doctor and patient which is the root principle of medical practice to-day in this country. In other words, it must be built up on a general practitioner basis.

I would plead to-day that the teaching hospitals should pay special attention to the needs of those students who intend to engage in general practice.

Have you ever considered the relation between the student and his teachers in this respect? Three-quarters of the students of a hospital will pass into general practice, and in the whole course of their preparation for this career, never once have they been taught or examined by anyone who has had experience in this kind of work. Is it not time that this fact was faced? If the answer is that the existing system is the best, let us at least know the reason why.

I hold that there is no better service that you can render to the public and the State than to turn out a good type of G.P., and I would like to see medical education primarily directed to this end. And I venture to ask this question. Could not the altered outlook I have mentioned possibly afford some solution of the curriculum problem? The medical student spends much time over detail which is of no real use to him as a general practitioner, and this time could be spent with advantage on subjects a knowledge of which is essential in general practice and which at present he has to acquire after he has qualified.

It has always seemed to me an anomaly that in an institution like St. George's, which in a sense is a factory engaged in large measure in producing the best type of general practitioner, there should be no place on the staff or in the teaching machinery for a general practitioner *as such*. A knowledge of general practice would be of definite advantage to every member of the profession whatever his specialty; but if there is one class more than another to which this applies it is to those who teach and examine our students. The difference between hospital and general practice is wide and important, and I am sure that something could be done to prepare the newly qualified for the difficulties he will have to face in general practice. Somewhere in the out-patient department, especially, there would seem to be room for a general practitioner's special knowledge, not only in a teaching capacity but possibly as an aid to a sifting process which would help to ensure that abuses of the department were checked. Whether such facilities, if available, would appeal to the student, experience alone can determine, for the natural aim of the student is to pass his examination, and he will look upon any case in the light of its value for examination purposes rather than its practical utility in his later career. The line of distinction, however, is not, after all, clear cut, and I am convinced that an experiment on these lines is worth while.

I would also make a strong appeal for special instruction in National Health Insurance work. It seems hard to believe in, and still more to defend, a system which ignores completely, in its teaching capacity, a State contract which every registered medical man is free to join the moment he is qualified, which, as I have stated, has been entered into by 15,000 doctors at the present time. Luckily in this case a few lectures can cover the most important difficulties, such as the regulations governing certification, prescribing, and record keeping. This service offers a quick entry into general practice, and I often think that the service is least understood by those of our own profession who are outside it. The old idea that the panel service is a step towards a whole-time State medical service is the exact opposite to the truth. It is, in fact, our greatest safeguard against it. It is a recognition by the State that a general practitioner service with free choice as between doctor and patient is the best system of medical attendance. The service should have the sympathy and goodwill of every member of the profession, for the most obvious reasons. If I am wrong in the view I hold, then I say the profession has been put to the test and failed, and that a State medical service, with the inevitable cleavage of the profession into factions, is the only possible line along which to expect future development.

At the present moment the State is committed to supply a general practitioner service to some 15,000,000 of the population of England, Scotland, and Wales, and has contracted with nearly 15,000 doctors to that end. The National Health Insurance service, though not without its imperfections, has been and is a success, though it works least satisfactorily in densely populated areas. Like so many institutions in this world (such as married life) you hear all about its failures and little enough of its success. It is not sufficiently recognised that National Health Insurance is a great scheme of *preventive medicine*. The doctor has every inducement to keep his patients well. The general practitioner is growing a little tired of having the words preventive medicine continually put to him as something new that he has never thought about. Preventive medicine means nothing more than the education of the public in the art of keeping well. The general practitioner has been doing this, as he does most of his work, quietly, steadily, and effectively, without making a fuss about it, from time immemorial.

Many of the hospitals of this country are in process of extending their scope in order to supply the needs of people of modest means. Contributory schemes are becoming universal, and special hospitals for this class of patient are increasing rapidly. In such a development it is inconceivable that the general practitioner should have no place. Somewhere and somehow you must avail yourself of his services to do the work he is well capable of doing. There are many difficulties but they are, I think, exaggerated and altogether insignificant in comparison to the principle at stake. Leave him out and you will encourage him to find a substitute for your hospital which will not break the personal tie between patient and doctor, or at least tempt him to avoid using your institution as far as possible. Leave him out and in some areas, I am sure, you will run grave risk of dividing the local profession into two parties, to the detriment of both. Leave him out and you will deprive him of a most important means of keeping himself efficient and improving his value as a doctor.

The profession recognises that the hospitals must have all the material they want for teaching purposes; that every case of emergency or difficulty must continue to have free access to their doors; that nothing must ever be done to damage in the least their wonderful record of response to the needs of the sick. But if they make claim for increased support on the grounds of the steady increase of their out-patient work, and ask for sympathy for an overworked specialist staff, they must satisfy the profession at least that they are not encumbering their machinery with unnecessary work. If they spend money and the time of a specialist staff on work that can be just as well done by outside general practitioners, and for which provision has already been made by the State, they deserve as little sympathy in that respect as the general practitioner who takes advantage of their charity to escape his own obligations.

COLLEGIATE LIFE AND CLINICAL STUDIES

By W. R. Halliday, LL.D.

PRINCIPAL OF KING'S COLLEGE, LONDON

I am not going to pronounce upon the vexed question of larger and smaller clinical medical schools, though there seems to a layman a very valid line of argument which the smaller clinical schools can put forward. But I should like to say a word upon the merits and defects of the system by which the pre-clinical years of study are spent at a college, whether in Oxford or Cambridge or London and the clinical years in a hospital.

The supreme educational merit, as it seems to me, of this divided system is that the student—usually young, for the complete medical course is long—does his earlier years in close contact with students of other subjects and other faculties than his own and is not too early completely immersed in a professional milieu. For individuals—for we all know that some of the richest harvest of our university experience was derived not from the class-room but from sharpening our minds on and exchanging ideas with our fellow-students—I believe this contact to be of the very highest possible educational value. For medical science, as it advances, it is becoming more and more important to be at least on nodding terms with sciences not merely contiguous but already forming part of it. I think of the fact that at King's one of our readers in physics has taken a medical degree in his spare time and is now doing important work as consulting physicist to one of the London hospitals, while another of the younger members of the physics staff is leaving us to become a doctor.

The disadvantage in the severance of the scientific (if I may so call it for convenience) and the clinical stage is that some students may not adequately get their connexion into their system. They may learn up their anatomy and physiology, pass the Second M.B., and think they have finished with them. They will only be so foolish if when learning their anatomy and physiology they have regarded them as so much academic stuff to get up in order to answer questions in an examination paper. In King's College we are anxious as far as possible to obviate this danger to the weaker vessels. We are grateful to Mr. Macleod and Dr. Warner, and to those clinicians belonging to the other hospital medical schools with which we are especially associated, who have accepted honorary positions on our staff and so bring into the class-rooms of preparation for the Second M.B. the realisation that the science there learned is to be clinically applied. Equally our College teachers have tried, so far as possible, to help the clinical medical schools with lectures to remind students at a later stage that clinical practice and the successful treatment of particular cases rest upon the fundamental principles of science.

A great many of the most important things in higher education and research are so much a matter of atmosphere and attitude of mind that it is difficult briefly to make their value clear in a few words. I am personally sure that the indirect influence of mixing up medical students with students of other faculties is of the very greatest value. Similarly, I attach the very greatest importance to the coöperation which we are doing our best to promote between the staff of the College and the clinicians in the hospital medical schools. We are fully alive in the College to the danger of academic teaching in the medical sciences becoming divorced from "real life." The free interchange of thought and coöperation in research between clinical and pre-clinical teachers will be promoted in the College by any means in our power, and I am glad to think that our new Hambleden department of anatomy, which was opened last year, will provide on our side the necessary laboratory equipment for doing our full share in carrying this ideal yet further than we have been able to do in the past.

MIND AND BODY

By Douglas McAlpine, F.R.C.P.

PHYSICIAN IN CHARGE OF THE NEUROLOGICAL DEPARTMENT, MIDDLESEX HOSPITAL

Freud's views may be briefly summarised as follows. Everyone has within him certain instinctive feelings. Some of these feelings and wishes are felt to be wrongful or unpleasant—that is to say, they cannot be reconciled with the person's idea of right or wrong, or they may offend his pride. They are therefore relegated to the unconscious by a process of forgetting or (to use the psychological word) repression. If this process is only partially successful it will produce a state of mental discomfort which may in certain individuals lead to the development of a neurosis. According to Freud the neurotic is the person who instead of attempting consciously to find a solution for his problem shoves it aside or represses it. Treatment consists in bringing these conflicts to the surface and persuading the patient to face them. This constitutes psycho-analysis, and credit must be given to Freud as one of its earliest exponents. Unfortunately he overstressed the part played by sex in the ordinary individual's life, and this undoubtedly had a prejudicial effect on the acceptance of psycho-analysis by both the medical profession and the lay public.

Adler, a former pupil of Freud, lays especial stress on the fact that no two people are alike mentally as well as physically, and that it is necessary to study each case separately. The name "individual psychology" has been given to this school which at present has many adherents in this as well as in other countries. Briefly, Adler's teaching holds that a person's character, or as he calls it "style of life," is formed during the first eight years of life and that an adult will react to his difficulties in the same manner as he did in childhood. The normal person faces difficulties in a common-sense way. He depends upon courage or confidence which has been built up by experience in childhood and upon a feeling of secure membership of the human family, a feeling which depends upon the harmony of his own life.

Family life represents on a minor scale what social life will be when the child grows up. The adult neurotic is the product of an abnormal attitude to life adopted in childhood.

Can neuroses be prevented and can they be cured? The answer, I think, to both of these questions is in the affirmative. The past 20 years have created a feeling of insecurity largely attributable to the war and the disappointments of peace. People have been subjected to unusual strain and it is little wonder that many have broken down. Most of us are potential neurotics and therefore we should understand and by encouragement help those who either by their parentage, upbringing, or circumstances, have lagged behind in the race of life. The principal duty of parents towards their children is to teach them at an early age to have courage. Most young children are fearless, they become frightened of situations by the remarks and attitude of their parents. If every anxious parent realised that the child's mental development was of more importance than his physical health and the part which he or she played in the formation of a child's character, there would be far less unhappy and many more useful people in the future. Educational authorities are awakening to the importance of psychological principles in the teaching of children, and that a class of children cannot be taught according to methods of mass-production, but that each member of that class has an individual personality, and that the successful inculcation of self-confidence into each child depends on a teacher's appreciation of this fact.

There ought to be wider facilities for psychological treatment of children and their mothers. As far as I am aware there are at present only two hospitals in London where special clinics of this sort exist.

Treatment may take one of two forms, suggestion and persuasion or some form of psycho-analysis. Suggestion is a method of treatment which has been used by physicians ever since they began to practise the art of medicine. The mere assurance of a doctor that there is nothing seriously wrong and that the patient will lose his symptoms has always a beneficial effect on the neurotic subject. Allied to suggestion is persuasion. This method was used by Dr. Hurst and others during the war. Soldiers suffering from hysterical paralyses were made to walk in a day, sight was restored to the blind, and hearing to the deaf. In other days and times such cures would have been spoken of as miracles. The same methods of suggestion and persuasion applied in civil life are not always so successful. In the war cases the explanation was not difficult to find—namely, the fear of war. In civil life the cause of the symptoms may be obscure and it is necessary to hear the patient's life story and to show him how and where he has failed and the path he must tread in the future. The mention of psycho-analysis to a patient often conjures up in his mind the thought of a painful confession in which the patient is subjected to a severe cross-examination chiefly on sexual topics. I have tried to make it clear that modern psychotherapy is not concerned paramountly with sex, but with the person's life pattern as formed in childhood and his reactions to difficulties later. Such an inquiry requires to be carried out first and foremost by a doctor who feels sympathetically towards the patient. Apart from exceptional cases it requires no advanced technique beyond a working knowledge of psychological principles.

Those of you who are commencing your medical studies will soon be interested in the study of the human body and its reaction to disease. Try from the first to remember that, however interesting the case may be from the organic point of view, the patient has also a mind. When you enter upon practice you may find that most of the interesting conditions you saw in hospital never seem to come your way. Indeed, many of your patients will complain of "nerves" or of symptoms for which you can find no cause. Such a patient is almost certain to be up against some problem which he is evading. You will, I hope, attempt to ascertain the nature of his problem. In the majority of cases you will be able to make the patient know himself and understand how his symptoms have developed. You will encourage him to face his difficulties and sometimes you may have the satisfaction of seeing him recover his health and happiness.

It may be objected that the general practitioner has no time for this sort of thing. Surely it is much better in the long run to spend an hour with a patient on two or three occasions with a chance of doing him some good than to hope that bottles of physic may cure him. You will meet with cases that do not respond to this simple psychological treatment. These you should send to the psychological department of a hospital or a specialist in psychotherapy. But the general practitioner as family physician is best suited to handle early cases of neurosis in adults and children.

INFECTIOUS DISEASE

IN ENGLAND AND WALES DURING THE WEEK ENDED SEPT. 24TH, 1932

Notifications.—The following cases of infectious disease were notified during the week:—Small-pox. 7 (last week 19); scarlet fever, 1613; diphtheria. 908; enteric fever, 94; acute pneumonia (primary or influenzal), 465; puerperal fever, 44; puerperal pyrexia, 103; cerebro-spinal fever, 36; acute poliomyelitis, 33; acute polio-encephalitis, 8; encephalitis lethargica. 11; continued fever, 1 (Winsford, Cheshire); dysentery. 15; ophthalmia neonatorum. 72. No case of cholera, plague, or typhus fever was notified during the week.

The number of cases in the Infectious Hospitals of the London County Council on Sept. 27th–28th was as follows:—Small-pox. 27 under treatment, 2 under observation (last week 22 in all); scarlet fever, 1303; diphtheria, 1418; enteric fever, 23; measles, 269; whooping-cough, 349; puerperal fever, 24 (plus 10 babies); encephalitis lethargica. 231; poliomyelitis, 5; "other diseases" 147. At St. Margaret's Hospital there were 16 babies (plus 10 mothers) with ophthalmia neonatorum.

Deaths.—In 117 great towns, including London, there was no death from small-pox. 2 (0) from enteric fever, 4 (0) from measles, 6 (2) from scarlet fever, 15 (2) from whooping-cough. 24 (7) from diphtheria. 68 (16) from diarrhœa and enteritis under two years. and 7 (1) from influenza. The figures in parentheses are those for London itself.

The deaths from diarrhœa are diminishing. the acme having been reached in the week ended *Sept. 10th*. when the number was 89 for the great towns and 29 for London; Liverpool still stands highest with 14 deaths, West Ham following with 3, no other town reporting more than 2. East Ham and Walthamstow each reported 1 death from enteric fever. The fatal cases of diphtheria were widely distributed. 2 each being reported from East Ham, Liverpool, and Salford.

The number of stillbirths notified during the week was 261 (corresponding to a rate of 42 per 1000 total births). including 43 in London.

POST-GRADUATE LECTURES

WE continue this week the publication of abstracts of some of the lectures delivered at the autumn post-graduate courses of the London teaching hospitals. Those summarised below were delivered at St. Mary's (Mr. Leslie Williams and Dr. Reginald Miller), King's (Mr. Yates Bell), and Charing Cross (Mr. Crook).

ANALGESIA AND ANÆSTHESIA IN OBSTETRICS

(MR. LESLIE WILLIAMS)

IN discussing this question we must realise that considerable progress has been made in recent years. No longer is the parturient woman expected to bear the pains of labour as the natural thing; nor is a whiff of chloroform towards the end of the second stage accepted nowadays as a reasonable palliative. In fact, I think we are trying to travel too fast along a difficult path and, though advance and research in the relief of pain in childbirth is admirable in the hands of qualified and skilled practitioners of medicine, personally I deprecate the present tendency towards the widespread exhibition of analgesic drugs and anæsthetics by midwives. For the administration of an anæsthetic always requires skill and experience, and in obstetrics the judgment of dosage is extremely difficult if one is to strike the balance between preservation of uterine contractions and absence of memory of suffering.

Passing to practical methods which can be used by practitioners, I think the most generally useful analgesic for the *first stage of labour* is morphia and scopolamine. I advise morphia gr. ¼ and scopolamine gr. 1/100 as soon as the pains are really beginning to cause distress. This is often found to be at the time when the cervix is completely "taken up" and dilated to about two shillings. Subsequent doses of scopolamine gr. 1/450 can then be given at intervals of one to two hours, and usually the degree of analgesia and amnesia thus obtained is fairly satisfactory. However, the estimation of the quantity of the drug required for any individual patient is very difficult, and, if the method is to be pushed to the fullest, the complete "twilight sleep" technique may be adopted. In this the time for the administration of the repeated scopolamine doses is judged by means of a "memory test" and too much notice must not be taken of the appearance of suffering during a pain if the patient sleeps in the intervals. A few words of warning are, however, necessary. The "twilight sleep" patient must never be left unattended for a single moment. One of the reasons for this is that they become very thirsty, and even if given drinks, they may, if left alone, get out of bed in a semi-conscious condition and drink any antiseptic lotion that may be lying about. Again, the condition of the bladder must be watched very carefully and catheterisation employed when necessary. In some cases violent mental excitement is manifested, and in these, as in others in which overdosage is indicated by an increased pulse-rate and slowing of the respiration, the hyoscine must be stopped immediately. In cases which are responding well the scopolamine injections may be continued for many hours and even throughout the second stage, but it is customary when the head appears at the vulva to discontinue the twilight sleep and to change over to one of the anæsthetics which I shall shortly describe as being of value in the expulsive period.

Among other objections which have been raised against morphine-scopolamine analgesia is that the child is born in a state of apnœa. True; but I feel that all such children will, if suitably treated, recover. The suitable treatment consists essentially in keeping the child still and warm, clearing the air-passages, giving stimulants, the administration of 6 per cent. carbon dioxide in oxygen, and, above all, the avoidance of violent methods of artificial respiration.

Recently the various barbiturate preparations have been extensively employed, and perhaps the most widely used has been Nembutal. With this drug I have had some very satisfactory cases and some very unsatisfactory ones. Some of the best results have been obtained by the following scheme of dosage. Morphia gr. ¼ and scopolamine gr. 1/100 are given when the pains are first causing real distress. This is usually followed by sleep, and on awakening the pains again become regular and strong and are associated with more or less distress. At this point two capsules (grs. 3) of nembutal are given, and are immediately followed by a drink of water as hot as the patient can drink. I think this helps to dissolve the capsule and to assist the absorption of the drug. A third capsule may be given three hours later if the patient is obviously losing the effect of the first dose, and a fourth a further three hours later. Generally speaking I do not think this dosage of four capsules (grs. 6) should be exceeded, and in a fortunate case the labour is nearly terminated and the suffering of the remaining expulsive pains can be relieved by chloroform or gas-and-oxygen.

I have tried the method of giving nembutal and chloral as described by J. V. O'Sullivan and W. W. Craner[1] but have not been very successful, and in my experience it has no advantages over nembutal alone. And I repeat that nembutal is by no means ideal since there is an enormous variation in its effects on various people, and in using it I have a very definite fear of causing poisoning.

Sodium amytal should theoretically be superior to nembutal for obstetrics since its action is less intense but more prolonged. It can be given in approximately double the dose of nembutal and the doses spaced further apart. I have little experience of this drug at present. Avertin might be used, and has, in fact, been extensively tried in obstetrics, though more for the second stage than for the first; but rectal administration of a drug and the subsequent spilling of some with the descent of the head is a disadvantage. Personally I think there is no place in obstetrics for the intravenous administration of nembutal, &c. Apart from the well-known dangers, the action of the drug is much too short-lived to be of use in counteracting the prolonged suffering of childbirth.

Finally, before proceeding to discuss briefly anæsthetics for the second stage of labour, I should like to draw the attention of those who can study the technique in hospitals to the Gwathmey method. In this, morphia has its action intensified and prolonged by being given intramuscularly in 2 c.cm. of 50 per cent. magnesium sulphate solution. Two further injections of the magnesium sulphate solution alone are given during the first stage, and just before the second stage a mixture of ether and olive oil is injected into the rectum.

In the *second stage of labour* the best anæsthetic is gas-and-oxygen. It is given with the onset of each pain, and the patient is allowed to regain consciousness in between. As in everything else, there are disadvantages: the apparatus is heavy and bulky, the services of a skilled anæsthetist are required for a prolonged period of time, and—a point often overlooked—the patient wakes up after each administration and asks pitifully "is it all over yet?" However, with all its disadvantages, it is still the best, and the alternatives of chloroform, usually given from a Junker's apparatus by the nurse under the supervision of the obstetrician, or better, ether or other inhalation anæsthetic administered by an anæsthetist, have the disadvantage that uterine contractions are seriously interfered with unless the minimum useful dosage only is given, and that only during the pains. Furthermore, the child is often born to some degree anæsthetised.

---

[1] See THE LANCET, 1932, i., 119, 263, 1175; also July 23rd, p. 182.

For some time past at many hospitals experiments have been made with 20-minim capsules of chloroform, wrapped in several thicknesses of lint which, when broken, allows the parturient woman to inhale the chloroform vapour from the packet; the capsule is held over her mouth either by herself or by a nurse in attendance. This method has been devised in the hope that it will enable midwives to relieve the sufferings of patients in their charge. I hope it will be found to be successful, but having tried the inhalations myself, I am rather afraid that there may be accidents from the inhalation of too concentrated a vapour. However, results will show, and in the cases I have seen the relief of pain seems to have been considerable.

I do not propose to-day to deal with extradural or spinal analgesia in obstetrics, for these are methods useful chiefly in hospital practice.

TREATMENT OF COLI BACILLURIA AND PYELITIS

(Mr. YATES BELL)

I PROPOSE to dismiss the treatment of the acute condition in a few words. The patient must, of course, be confined to bed between blankets and remain in bed until the temperature has been normal for at least seven days. Sweating is to be encouraged by means of hot-water bottles, but diaphoretic drugs are now eyed with disfavour; an initial purge should be given, but excess of purgation after this is to be avoided. In the diet, fluids only are allowed at first and here it must be emphasised that milk is to be excluded absolutely until recovery is complete; as the patient improves the intake may be increased with fruit, vegetables, and carbohydrates, and then with chicken—other meats and milk being disallowed until complete recovery. Alkalis, with belladonna, must be administered until the temperature has been normal for at least two days and, as Frank Kidd pointed out, it is wise for the doctor to visit the patient frequently to test the urine with litmus and increase the dose of citrates, &c., until the urine is well alkaline. When the febrile state is over, a course of urinary antiseptics should be started and this should be continued for three months; the various drugs and their methods of administration I will refer to later.

Chronic *coli* bacilluria I deem to include delayed resolution after a first acute attack and repeated exacerbations (which may of themselves be acute or subacute) of a mild or latent infection. Any pyrexial attack must be treated under the rules given for the acute condition, but when the fever disappears the case should be treated under the following scheme: in chronic *coli* bacilluria I do not include gross disease such as infection complicating enlarged prostate or stone in the bladder; nevertheless, such conditions must first be excluded by careful clinical, cystoscopic, and radiological examinations. Assuming the infection to be so-called primary, it is still important to search for a possible focus. The appendix is often at fault, less commonly the nasal sinuses, tonsils, and teeth; the large bowel may be to blame.

It is my principle to attack these chronic coli bacilluria cases with three groups of treatment which I will call (*A*), (*B*), (*C*).

(*A*) Firstly a combination of *general hygiene, diet,* and *drugs* must be tried. Attend to the large bowel; it is just as important to avoid diarrhœa and fluid motions as it is to avoid constipation. Salol grs. 10 or hydrarg. c. cret. gr. ½ may be given t.d.s. as intestinal antiseptics. Milk and red meats should be avoided; fluids should be taken freely at all times, and lactose (2 oz.) may be given daily to promote the natural growth of *B. acidophilus* in the intestine. Drugs are the same as have been known for some years, but more attention is being paid to the reaction of the urine while such drugs are being administered. The colon bacillus is inhibited by an alkaline urine (neutral pH 7) or by an acid urine when the pH drops below about 5·6. It is therefore important to pay more attention than has been the custom to the reaction of the urine, testing with litmus; the urine must be shown to be very acid or very alkaline, according to the drugs being given in association at that time.

(*a*) Alkalis are the usual potassium citrate, potassium bicarbonate, and sodium bicarbonate. They must be given in doses large enough to render the urine strongly alkaline.

(*b*) *Acid sodium phosphate* is still the most popular acidifier of the urine and it does increase the amount of acid radicles therein but it does not increase the hydrogen-ion concentration sufficiently (depress the pH) in many cases. The dose usually given is grs. 30 t.d.s., but this is often insufficient; as much as grs. 150 may be given t.d.s., the sign of overdose being diarrhœa due to its salt action on the bowel. It should be given before meals, with the antiseptic after meals, for its excretion in the urine is slower. Benzoates and salicylates are similar but much less effective.

(*c*) *Ammonium chloride* grs. 20 t.d.s. in a mixture with the urinary antiseptic is good and will give a lower pH in the urine than can be obtained with acid sodium phosphate.

(*d*) *Ammonium nitrate* 0·5 g. in a keratin-coated capsule is effective. Twelve capsules are given during the day. The urine can be best acidified by this method.

(*e*) *Hexamine* to be given with an acid urine is still the most effective of the urinary antiseptics. It is probably best prescribed in a mixture with ammonium chloride and extr. glycorrhizæ liq.

(*f*) *Cystopurin*, a combination of hexamine and sodium acetate, is less irritant than hexamine, and may be prescribed for those people whose digestions are upset by hexamine.

(*g*) *Hexyl resorcinol* should be given in capsule form increasing the dose to 3 capsules t.d.s.; during its administration fluids should be restricted and no alkalis given, for its action depends largely on surface tension.

(*h*) *Methylene-blue* in a pill of grs. 3 is useful, especially as it may be administered in association with an alkaline prescription.

(*i*) *Mercurochrome*, 4 mg. per kg. of body-weight, is given intravenously; but it is sometimes toxic and not without danger, and in my opinion its advantages do not outweigh the risks.

(*j*) *Neutral acriflavine* gr. ½ t.d.s., as a tablet, is of definite use.

A scheme for administration of these drugs should be on the following lines: An alkaline mixture for a fortnight, then an acid mixture for six weeks, giving hexamine for the first two weeks, hexyl resorcinol for the next two weeks, and acriflavine or cystopurin for the third two weeks. Drugs and hygiene should be continued for two months, and if there is improvement this cycle may be repeated; but if there is no improvement other means must be tried.

Vaccines, in my opinion, are a definitely helpful adjunct and that view I believe is now generally held. It is my custom to give vaccine treatment coincidently with the diet and drug course, but this is not always possible in general practice and where the number of hospital out-patients is very great;

where difficulties arise vaccine should be reserved for cases not responding after two months' drug treatment and then combined with a further course of these urinary antiseptics. The vaccine must be autogenous and the dosage small; it is my rule to begin with half a million, increasing up to five million, and eventually to ten million at intervals of ten days. The urine for vaccine preparation must be obtained through catheters from which any sterilising antiseptic—e.g., biniodide or formalin—has been removed by sterile water or saline; even traces will inhibit the growth of bacteria in culture.

(*B*) *Lavage of the renal pelvis* should be the next line of attack in cases of failure of drugs and vaccine. It is now a definitely established treatment, thanks largely to the work of Frank Kidd. It should be done by an experienced urologist and reserved for chronic cases except in exacerbations of acute pyelitis of pregnancy. The pelvis is washed out with sterile saline through a ureteric catheter and 4 c.cm. of 1 per cent. silver nitrate or 5 per cent. colloid silver is installed into the renal pelvis; the catheter is then withdrawn, allowing the antiseptic fluid to escape gradually. The treatment may be repeated at seven-day intervals and as many as six or ten wash-outs may be given.

(*C*) *Ketogenic diet.*—This is a new and very promising method of treatment. Owing to the nature of the diet it is necessary to carry it out in consultation with a biochemist; this very fact, of course, will cause the treatment to be reserved for cases that have not responded to more convenient methods; but it has given marvellous results when carefully applied. It depends on the replacement of the carbohydrates in the diet by fat until ketones are present in the urine as indicated by the ferric chloride test. It is not quite certain whether there is an antiseptic virtue in the ketones, or whether it is the associated lowering of the pH (increase in acidity); but apparently the best results are obtained when the pH is low and it is customary to combine the diet with the administration of ammonium nitrate in 0·5 g. enteric-coated tablets (12 a day). It is also essential that the patient can physically digest such a fat diet. The patient must be admitted to an institution for three or four days to allow the biochemist to work out the diet appropriate; he is then allowed to go home, but he must keep strictly to the diet for a month, after which a gradual increased leniency is allowed.

Bacteriophage treatment I mention merely for completeness. Very few writers now claim successes, and these are chiefly in acute cases which would probably recover without the bacteriophage. Bacteriophage is probably of little help in chronic cases, and I do not think its value justifies its use.

SOME SCHOOL PROBLEMS IN PRIVATE PRACTICE

(DR. REGINALD MILLER)

CHILDREN of well-to-do parents are at school for some ten or eleven years, and these years cover most important periods of physical and mental development. We cannot therefore, as doctors, afford to neglect the problems that may arise in connexion with school life, even though they are often of only indirect medical interest. We should not regard the school years as a time of unavoidable strain and difficulty for a child; rather should we think of them as an opportunity to benefit the child in every way. Often, as we know, in the case of a delicate town-bred child, the wise choice of the right boarding-school is the one thing that sets the child up in health. It is, then, with the idea that the very best use should be made of a child's school years that I discuss just a few of the difficulties which may lead to incomplete success or even failure.

To take first the choice of a school for an individual child. The preparatory schools for boys and the private and public schools for girls exist in an atmosphere of considerable competition. There is no need for parents to be dissatisfied with the child's school: there are many more to choose from. As a matter of fact, in the best of these schools the standard is extraordinarily high. The great public schools for boys are more outside this commercial competition, but they have their great traditions to sustain them. In choosing a school it must be remembered that every school has its periods of ups and downs. Taken as a whole, day-school is more of a strain on a child than boarding-school. It necessitates often very long hours, keeping up a dual set of interests, and is lacking in the fuller life of the boarding-school. The solitary child should certainly go to boarding-school, and the same may be said of the delicate town child. In this case the right climate should be chosen, and its good effect can hardly be over-estimated. There are many preparatory schools which may be absolutely trusted to attend to the needs of a delicate child, often with most gratifying results.

Secondly, to get the best results of school on a child's health and character, the school and the parents should coöperate, playing into each other's hands for the sake of the child. Unfortunately, this coöperation is in many cases never established. Parents are apt to regard their own child too much as an individual; whereas the head of a school, while desiring to give individual attention to each child, has to set the tone of the school as a whole. Parents should not be jealous of this. If they thought the matter out they would realise that they do not send their child to school to learn merely lessons, but a great many other things, all of which depend on the atmosphere or tone of the school. It is within the atmosphere of sensible discipline that the child gets freedom from being corrected and dragooned, and it is because of this atmosphere, acting insensibly and automatically, that the child learns to choose for itself to behave sensibly, unselfishly, and so on. Parents should be ready to tell the head of a school their difficulties with their own child, and should not be hurt when they are told of the child's faults at school.

Lastly, of more directly medical interest is the question of fatigue brought about by the strain of school life. The effects of this are largely seen in connexion with the nervous system of a child. It may become dull, apparently lazy, and lose its place in the class; or in the case of highly strung children, it becomes restless, emotional, irritable, wildly disobedient, and negative. Some of the causes of such fatigue lie in the child itself, but others come from the school régime. Of the latter may be mentioned too long hours, too much noise and ragging, too much activity before breakfast, and, in the case of older children, possibly too short hours of sleep and insufficient or improper food at night. The strain of examinations, now that all public examinations are to a large extent competitive, is capable of doing children great harm. These effects of fatigue, as has already been said, are largely shown in connexion with the nervous system by alterations in mental capacity, behaviour, and so on; and there is a tendency amongst some of the medical profession to suggest it is the school doctor's part to spot, study, and treat cases of this type. As far as normal children, as opposed to psychopathic children, are concerned, I think this would be a mistake. Left to themselves and rested, these children will right themselves. Too much apparent interest in their failings is harmful, whether this interest is taken by the school-teachers or the doctor. In any case, no school doctor can be in sufficiently close contact with the child to see the early signs and symptoms of over-fatigue, and from the responsibility of being able to spot the tired child and differentiate it from the wilfully lazy or naughty child, school-teachers cannot possibly escape.

ON THE TREATMENT OF RECTAL DISEASE

(MR. ERIC CROOK)

THE *ischiorectal fossa* is a part of the body particularly liable to infection. It is filled with fatty tissue which is continually altering in shape, with the degree of distension of the rectum, and it is not well supplied with blood-vessels. Moreover, it is near to a source of infection; indeed, nearly all infective lesions of the fossa are caused by organisms from the bowel. Very often infection travels by way of a fissure. Suppuration may take place in the fossa without easily detectable physical signs; for the fatty tissue can adapt itself to pressure, the skin over this region is thick, and the subcutaneous tissue is dense, so that many ounces of pus may be present without obvious signs. Early incision, however, is essential to successful treatment and the prevention of fistula formation. Extension of infection leads to necrosis of fat. Cases in which there is brawny swelling and fluctuation are easy to recognise, but in others there may be only tenderness on pressure and no fluctuation. A rise of temperature and leucocytosis, in association with tenderness in the ischiorectal fossa, should suggest suppuration. There may be no signs other than slight asymmetry of the ischiorectal fossæ that can be detected with the patient in the genupectoral position, and the exploratory needle gives valuable information in doubtful cases. The incision should not only be T-shaped, but the two right-angled flaps at the junction of the vertical stroke with cross-bar of the T should be cut away to give free drainage and to allow of granulation from below. Healing is usually rapid. Dry wool is desirable as the first dressing to check bleeding. After a few hours this should be replaced by a fomentation, and later moist dressings are the most comfortable; gauze soaked in hydrarg. perchlor. solution, 1 in 1000, laid upon the surface of the wound is satisfactory. In a doubtful case it is better to incise unnecessarily than to miss the presence of suppuration.

A distinction must be made between internal and external *hæmorrhoids*. Patients often come complaining of "an attack of piles," which often means that a small vein connecting the internal and external hæmorrhoidal plexuses has given way and formed a hæmatoma. This constitutes an external pile. On examination there is a bluish swelling ranging in size from the dimensions of an orange pip to those of a grape. It is tender on pressure, and is preventing the external sphincter from closing properly. An incision should be made under local anæsthesia to shell out the clot. An elliptical snip is made with scissors, and the groove left by removal of the clot usually heals readily. If left, the clot may suppurate or else contract, leaving a pellet of fibrous tissue, an anal tag. In internal hæmorrhoids the attack may be due to phlebitis with or without thrombosis. A large pale œdematous swelling prolapses and appears at the anal margin. It can be treated by local applications, but it is probably better not to defer operation. In the uncomplicated case opinions differ on the value of injection versus operative treatment of internal piles; with injection there is little discomfort, whereas the post-operative period is painful. On the other hand the results of operation are more permanent. Probably injection should be reserved for recent cases where the hæmorrhoids are no more than dilated veins; in old-standing cases there is much fibrous tissue, and injection results in formation of a pad of fibrous tissue which still has a tendency to be forced down through the anal sphincter; for such fibrotic cases operation is necessary. As with ischiorectal abscess, the best post-operative dressing for piles, internal or external, is a moist one. After applying hydrarg. perchlor. dressings for a week a change can be made to ung. hydrarg. subchlor.

Well over half the cases of *cancer of the rectum* coming up for treatment have reached the inoperable stage; the rectum, although highly sensitive in the lower part is relatively insensitive higher up. Although rectal cancer is not a rapidly growing variety it usually reaches an advanced stage without causing pain or discomfort. The scientific treatment is complete excision of the rectum and its lymphatic drainage by the abdomino-perineal method, but the case-mortality is high and the alternative treatment is perineal excision of the rectum following a previous colostomy. Where radical removal is impossible, attention must be given to relieving symptoms and reducing the discharge as much as possible. In those inoperable cases in which colostomy is performed the patient lives longer than in cases where no operation is undertaken. After colostomy the surface of the growth can be kept clean by washouts from below: pain, discharge, and the rate of spread are diminished, and in a few cases an apparently inoperable growth subsequently becomes operable as inflammatory induration round it subsides. In obstruction of the bowel by growth colostomy becomes imperative.

Palpation of the rectum is made easier if the patient lies on the right side and the left index-finger of the examiner is used. Owing to the anatomical relations of the pelvic colon, the examiner can palpate higher up with the patient on the right side rather than the left. In passing a proctoscope or sigmoidoscope the opposite holds good, because with the patient lying on the left side the bowel falls away from the nose of the instrument, which is therefore more easily passed.

HOSPITAL EXTENSIONS.—A new out-patient department has been added to the Victoria Jubilee Infirmary at Tynemouth with a sum of £15,000 bequeathed by the late Mrs. Wilson, of Easby House, North Shields. The building includes massage rooms, a theatre with anæsthetic room, sterilising room, recovery room, and other adjuncts. The warming is by radiation from the roof.—A casualty ward and staff bedrooms have been added to Faversham Cottage Hospital. Hitherto minor operations have usually had to be performed in the wards.—The Murton Street Home of the Sunderland district nursing association has been enlarged by the adaptation of an adjacent house. The work has cost £1300, of which £600 has been derived from the estate of the late Miss Emma Richardson.—Two maternity wards of five beds in all, which have been added to the Nairn Town and County Hospital, were opened last week by the Countess of Leven and Melville. A legacy of £4350 left by the late Mr. Andrew Morison, of Nairn, provided most of the cost, which amounted to about £5000.

MEDICINE AND THE LAW

Septic Abortion: Coroner's Suspicions

AT an inquest last week upon the death of Eileen Woollard, an unmarried woman, 20 years of age, a verdict of "death from septic abortion" was recorded. The Paddington coroner, as will presently appear, found grave cause for suspecting that an illegal operation had been performed. The names of no fewer than six medical practitioners were mentioned during the inquest, and, while it was clear that the coroner made no reflection upon some of these, it was also clear that he was less than satisfied with the actions of others. The respective parts played by the six practitioners, who may for convenience be referred to as Drs. A, B, C, D, E, and F, are indicated in the following summary of the evidence. The dead girl became ill at Farnborough and stayed in bed for several days, Dr. A visiting her professionally in the evenings. On his advice her mother took her to London to consult Dr. B, who, on Wednesday, Sept. 14th, engaged a room for her at a nursing-home. Dr. B, described as an anæsthetist, was closely questioned by the coroner. He said he was not in general practice. "Why," inquired the coroner, "did a woman like Mrs. Woollard come up from Farnborough to see you, an anæsthetist, about her daughter who was unmarried and having an abortion?" "Because Dr. A sent her," replied Dr. B. "Why did he send her to you?" continued the coroner. The witness answered that Dr. A had to leave England and had no one else in London to whom he could send the patient. To resume the sequence of events, after engaging the room in the nursing home, Dr. B next day (Thursday) administered an anæsthetic and Dr. C operated. Dr. C was examined by the coroner as to his introduction into the case. He explained that Dr. B, in calling him in, said he had himself not yet seen the patient but gathered that it was either an incomplete abortion or a threatened miscarriage. The coroner suggested that there was a discrepancy between this version and what the witness had told the police. On the Friday Dr. B came to the nursing home several times. Dr. C also saw the patient that day, and found her very ill after the operation. Pressed by the coroner as to why he dropped out of the case at this point, Dr. C said he was not available later. Thereupon the coroner expressed his wonder whether perhaps Dr. C's object might not have been to avoid his name appearing on the death certificate. On this same day three fresh practitioners are introduced. Dr. D calls in Dr. E, who finds the patient suffering from septicæmia and peritonitis. Dr. E, in turn, calls in Dr. F. The latter concurring, Drs. E and F perform a further operation early on the Saturday morning, but the girl dies. The death certificate was signed by Dr. E, who was the last to see the patient alive.

Eileen Woollard died on Sept. 17th. On the 20th two women were found dead at Farnborough, in a gas-filled room. One was Eileen Woollard's mother, whom a detective-inspector had lately interviewed. The other was a foreign woman who had carried on business as a lady's hairdresser in Farnborough, and was understood to have studied medicine; there was reason to think that she knew of the dead girl's condition and was aware that she herself would be questioned by the police. The inquest upon these two women, both apparently troubled by financial anxieties, ended in a verdict of "suicide by coal-gas poisoning."

In concluding the Paddington inquest, Mr. Ingleby Oddie is reported to have described the case as a terrible tragedy "all arising out of this conspiracy to get rid of this girl's pregnancy, I am afraid by illegal means." "Everything seems to point," continued the coroner, "to this poor girl being subjected to criminal interference, with the result that she lost her life, her mother lost her life, and the Russian doctor lost her life. I have a pretty definite suspicion in my own mind as to what exactly took place; but, as it cannot be proved by direct evidence, and the circumstantial evidence is not sufficiently strong, the only course I can pursue with propriety is to record a verdict of 'death from septic abortion,' and leave the verdict open." No one will quarrel with Mr. Oddie's general observation: "So long as the law regards criminal abortion as a most serious felony, and regards the person who procures it and in procuring it causes death as being guilty of murder, so long is it the duty of a coroner to endeavour to find who was the person who performed an illegal operation in a case such as this."

PARIS

(FROM OUR OWN CORRESPONDENT)

CONTROL OF THE DANGEROUS LUNATIC

THOUGH the assassin of President Doumer has been beheaded on the assumption that he was responsible for his actions, this singularly tragic murder has focused attention on the problem of the lunatic who is a potential criminal. Psychiatrists, magistrates, and members of the legislative assemblies have conferred together and have decided on the creation of a Société de Prophylaxie Criminelle. It owes its birth to the initiative of Dr. Toulouse, medical director of the Henri Rousselle psychiatric hospital and president of the Ligue Nationale d'Hygiène Mentale, and he has been elected president of the new society. It has appointed nine different committees. The subjects with which they will deal are: (1) Parliamentary action; (2) organisation of criminal prophylaxis; (3) penitentiaries, reports of experts, and criminal psychiatry; (4) penal reform; (5) criminal biotypology; (6) the delinquent child; (7) social factors in crime; (8) sex criminology; and (9) alcoholism and the toxicomanias. At the first meeting Dr. Toulouse pointed out that criminals, who are usually abnormals and psychopaths, are wont to attract the attention of those about them by premonitory symptoms, such as abuse and threats of violence. These symptoms may not warrant the intervention of the law, but in certain cases they ought to be reported to centres of mental prophylaxis or psychiatric services. Appropriate action could then be taken under existing legislative measures. But in order that preventive control can be more effective than heretofore, new legislation, after a thorough psychiatric and juridical study, is necessary. It would seem that Belgium has already taken action on these lines.

THE PUBLIC SWIMMING-BATHS OF PARIS

Certain cases of conjunctivitis, some quite severe, allegedly traced to swimming-baths, have led to their ventilation, metaphorically speaking, in the press. A municipal councillor has requested the prefect of the Seine to answer certain specific questions with regard to the precautions taken to keep the water clean in the swimming-baths. In his reply the prefect has stated that the swimming-baths are fed either by water from artesian wells or by water which has been filtered and subjected to continuous chlorination. The walls of the swimming-baths are cleaned every morning with the help of electric aspirators, and every Monday the baths are emptied and cleaned. Samples of water are regularly taken by the authorities for analysis. The sanitary control of the Parisian swimming-baths thus seems to be satisfactory; and the officials can hardly be expected to catch the individual delinquent who, though he knows he is suffering from some infectious ailment, still insists on diluting his secretions and sharing them with his fellow-bathers.

B C G

B C G inoculation continues to hold the attention of the medical profession in France, where its merits have become, to a certain extent, a question of national honour. Accordingly, evidence throwing light on its value is being continuously collected with great assiduity. The latest report comes from Czechoslovakia, and is quoted by the *Presse Médicale.* After preliminary studies on animals, the State Institute of Hygiene in Czechoslovakia began in 1927 to prepare B C G, a sample of which was controlled in 1931 in Paris by Calmette, who found it to be identical with the Parisian B C G. Up to the end of 1931 a total of 2334 new-born infants had been vaccinated. With every supply of the vaccine sent to tuberculosis dispensaries, lying-in hospitals, and private practitioners, an elaborate questionary was sent. With its help it has been possible to follow the fate of 36·5 per cent. of the vaccinated infants up to the end of 1930. While the mortality among the controlled vaccinated infants was only 3·3 per cent., the general infantile mortality was as high as 14·6 per cent. It is, however, admitted that the vaccinated were as a class better cared for than the non-vaccinated.

IRELAND

(FROM OUR OWN CORRESPONDENT)

THE CORK MENTAL HOSPITAL DISPUTE

THE committee of the Cork Mental Hospital at its last meeting passed a resolution which must be almost unprecedented in the history of local authorities. The resolution proposed to fix the initial salary of the newly appointed resident medical superintendent at £450, instead of £750 at which the appointment was advertised. It may be remembered that when a vacancy occurred in the post the committee desired to promote its senior assistant medical officer, a man with long and excellent service in the institution. In order to do this, however, the approval of the Minister for Local Government and Public Health was requisite. The Minister refused such approval, and directed the committee to refer the appointment to the Appointments Commissioners for the recommendation of a candidate. The committee questioned the legality of the Minister's action in the courts of law, but their case failed. The matter was then referred to the Appointments Commissioners, and the salary fixed by the committee at £750 a year, rising by annual increments of £25 a year to a maximum of £900, was approved by the Minister, and the vacancy advertised on those terms. In due time the Appointments Commissioners recommended, and the committee appointed, a candidate other than the officer they had wished to promote. This is the ground recently put forward by the committee, the chairman and two other members dissenting, for altering the salary. Needless to say a contract cannot be broken so easily, and the Minister had already warned the committee that he would not sanction any variation of the salary. Notwithstanding this warning the committee passed the resolution. It is not likely that its action is a deliberate attempt of the committee to drive the new superintendent into resigning, though it is open to this interpretation. It is more likely to be a mere irresponsible expression of irritation at its wishes being over-ruled by the Minister.

MEDICAL DEFENCE UNION

Dr. W. S. A. *Griffith presided at the 44th annual* general meeting of the Union on Sept. 29th, when the report of the Council and the financial statement for 1931 were adopted. It was, he said, the second time he had occupied the chair after an interval of 30 years, during which the membership had increased fourfold. Of additional benefits granted to members in recent years he mentioned the following: (1) An indemnity insurance which provided unlimited cover in respect of damages or costs of the other side. (2) A reciprocal arrangement with the London and Counties Medical Protection Society by which one society will defend a member in an action brought against him as the result of the acts or omissions of an assistant who is a member of the other society. (3) A member of the Union is now defended against the acts or omissions of a bona-fide temporary locum tenens, a subordinate medical officer, or a non-medical assistant or subordinate in his proper sphere of work. (4) When a composite judgment is obtained for fees and costs, the fees due to a member are now regarded as the first claim on any payment received. (5) Any member who has paid 39 subscriptions may now compound for his future annual subscriptions by one payment of £1. (6) A member who employs an assistant not a member of either society may gain protection in actions brought against him by an additional annual subscription of 10s. During the last twelve months the Union, said Dr. Griffith, had defended an unusually large number of actions in the High Court; only in one case was a verdict given against a member. In the numerous allegations of negligence, raised against members in the county courts as a reason for not paying professional accounts, in not one instance was judgment given against a member of the Union. Defence against such allegations depended, he said, upon the evidence that can be placed before the court to rebut the allegation, and the prudent man should always have in mind the possibility of such allegations being made, and should avoid, as a matter of routine, any appearance of carelessness. The frequent employment of X ray and bacteriological examinations would constitute valuable evidence of painstaking and thoroughness. He stressed the imperative necessity of communicating without delay with the general secretary of the Union in all cases where complaints were made against a member. Many cases, he said, are prejudiced by unwise action taken before consulting him.

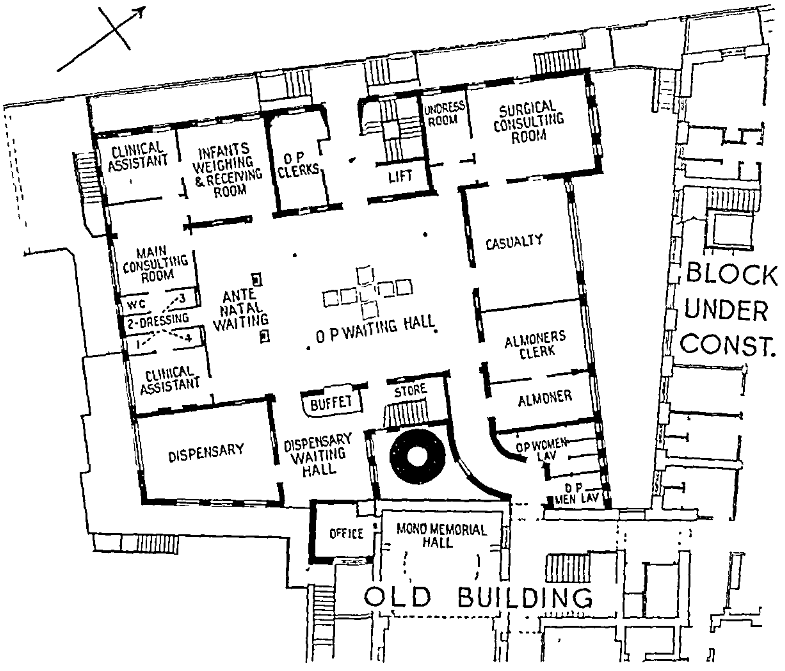
Sir Hamilton Ballance, Mr. F. C. Larkin, and Dr. E. Lewis Lilley, the retiring members of Council, were re-elected.

ST. LUKE'S MUNICIPAL HOSPITAL, BRADFORD.—In the operating theatre of this hospital white has been changed for green. The walls and windows are painted green, and the surgeons and nurses also wear that colour, on the ground that white strains the eyes and has a fatiguing effect.

AN OUT-PATIENT DEPARTMENT FOR CHILDREN

ADDITIONS TO THE INFANTS HOSPITAL

On Oct. 31st the new out-patient department of the Infants Hospital, Vincent-square, London, will be opened by the Princess Royal, president of the hospital. The department is the first part of the extension scheme to be completed; the scheme provides, in addition, for a new ward block for 76 patients, the reconstruction of the existing hospital, and the conversion of the old out-patient department into a new nurses' home. It was originally intended that the new out-patient department should make provision for ante-natal care of mothers, but owing to the economic depression, plans had to be curtailed. Apart from this omission the department has been equipped to meet the needs of the hospital, and the architect, Mr. C. Stanley Peach, has shown consideration for patients, doctors, and nurses alike in his design.



Ground-floor plan of the new block at the Infants Hospital, showing its relation to the old building and to the block still under construction.

The patient's point of view.—Mothers arriving at the department can park perambulators, with reasonable safety, in an alley-way between the new building and a neighbouring row of houses. They enter on the ground-floor level, and wait in the out-patients' hall which occupies the centre of the building and is lighted from above by a glass roof. The hall is rubber-floored and automatically heated. At one corner the dispensary waiting-room opens out of it, and here a buffet is provided at which mothers can fortify themselves with tea and buns. Doors from the hall lead into consulting-rooms, the weighing-room and the almoner's office. A gallery runs round the hall at the level of the first floor, and from this open ear, nose and throat, and eye departments, X ray and massage rooms, a room for light treatment, another for plastering, and a fully equipped theatre in which minor operations can be performed, and next to which a large recovery room has been set apart. Patients therefore need make no excursions to distant parts of the hospital when examination in a special department is required. In the basement, entered by a separate door, is a small blue-tiled chapel and a waiting-room for relatives.

The medical staff's point of view.—Each consulting-room is supplied with an X ray view-box lighted from behind and a basin with running water; heating is by the ceiling panel system, and gas fires are built into the wall for use in emergency. The ground floor consulting-rooms receive zenith light from skylights made by setting the first storey back a little from the ground floor. In the operating theatre the same method of lighting has been followed; air entering the theatre is filtered through cheese-cloth stretched on wire frames which can easily be taken out and cleaned. On the top floor, at roof level, is a diet kitchen and milk laboratory, entirely cut off from the part of the building used by patients. Milk will be stored in a large refrigerated cupboard. The basement contains a series of cubicles in which children found to have infectious diseases can wait until the ambulance comes for them. Behind the chapel is a mortuary and a pathological laboratory where post-mortem examinations can be carried out. Bodies will be placed in a refrigerated chamber.

The nurses' point of view.—An attempt has been made to avoid all unnecessary cleaning and polishing. The rubber or teak-block floors can be cleaned quickly with a mop; the door-handles are made of some sort of composition which actually defies cleaning. Even the stairs are slightly undercut to prevent dust collecting on their faces. A slight falling-off in this admirable principle may be observed in the brass hand-rail, but it is believed that constant use at the hands of the public will help to keep this burnished. Wire glass takes the place of railings on the stairs and round the central well. A special sloping slab is provided for the washing of napkins, and specimen napkins will be kept in small cupboards communicating by means of wire gauze with the outer air. The slats in the linen cupboards can be taken out and boiled; large heated cupboards are provided to warm blankets. All the doors are fitted with self-closing hinges and the walls are covered with cellulose paint.

General equipment.—The windows are made on a special design: the top and bottom panes are hinged along their upper and lower borders respectively, and open inwards to an angle of 45°. The central pane is divided into two lattices with vertical hinges. It is therefore possible to maintain ventilation by opening the top and bottom panes while avoiding any chance of being overlooked by closing the two central panes. A series of emergency batteries are being continuously charged and will come into action in case of failure of electric light power from the main. The equipment also includes water-softening, refrigerating, and ice-making apparatus. The new block communicates with the hospital on every floor, the passages entering the hospital between floors so that none of them are exactly on a level with the wards.

CORRESPONDENCE

SAFE MILK

To the Editor of THE LANCET

SIR,—In your issue of Sept. 24th (p. 707) Dr. Esther Carling raises the question as to what sort of milk the medical profession should recommend. The matter is of supreme importance, for the public is largely guided by the advice of its doctors, and yet few members of the medical profession seem to know the difference between the various designated milks. Your correspondent, after quoting certain figures—admittedly very disconcerting—showing the contamination of milk with tubercle bacilli, comes to the following conclusions: (*a*) there is no absolute safety anywhere; (*b*) ordinary mixed milk comes out better than Grade A; and (*c*) the more expensive type—Grade A (T.T.)—appears as rather less safe than pasteurised.

To the first conclusion I would reply that this is true of almost every foodstuff we consume, and does not apply only to milk. To the second, based on figures quoted from the investigations of Dr. Roodhouse Gloyne, I would remark that there is ample evidence to show that under proper control Grade A milk can be produced reasonably safe, and it seems possible that Dr. Gloyne's figures were based on too small a number of samples to be fully representative. The third assertion calls for comment. Dr. Gloyne is stated to have said that 3·8 per cent. of samples of Grade A (T.T.) milk were contaminated with tubercle bacilli, and the medical officer of health for Lewes questions whether such milk is free from risk for school-children. Now the chief medical officer of the Ministry of Health in his annual report for 1931 informs us that there were 195 Certified and 246 Grade A (T.T.) farms licensed that year. This gives a total of 441 farms where the cows are guaranteed to be free from tuberculosis. The number of samples of milk produced from these farms found to contain tubercle bacilli during the year was eight. As milk from each farm must have been examined many times during the period, the percentage of samples infected must thus have been much below the figure quoted. That even eight samples were found to be tuberculous is greatly to be deplored, and would appear to cast a reflection on the veterinary profession, which is responsible for testing the cows. In three of these cases cows known to have reacted to the test were kept on in the herd after they should have been rejected, and the contamination was thus due to breaches of the regulations and not to faulty testing; and yet in another case the licencee was purchasing ordinary milk from outside, contrary to the terms of his licence.

Under the regulations as they exist to-day a licence may be, and often is, given to a herd indicating its freedom from tuberculosis as the result of a single tuberculin test, provided always that any reacting cows have been removed from the herd. In already licensed herds new animals may be added after having passed one test only, even when they do not come from a tubercle-free herd. It is well known that cattle in the early incubative stages of the disease may fail to react to the test, and it is always possible that such animals may become infective before the next general prescribed test of the herd is carried out; and yet the veterinary surgeon who tests has no power to prevent the inclusion of such animals in the herd. Another danger which is frequently responsible for tuberculous cattle being found in so-called free herds is that there is no compulsory standardisation of tuberculin, and any brand may be used. The chief medical officer in his report above quoted makes the following statement:

> "No less than 16 different brands of tuberculin have been used in tests carried out under the regulations laid down by the Milk (Special Designations) Order, and about many of these no information is available as to their potency or reliability."

The veterinary profession has long been agitating for compulsory standardisation of tuberculin and that it should be made illegal to use any tuberculin not certified to be so standardised. It has approached the Government on more than one occasion to bring in legislation for this purpose, but so far without success.

Other alterations of the Order, which, in the opinion of our profession, would give a greater security against accidental infections, are also called for. It is felt by many, including medical officers of health, that if more use were made of the veterinary profession in the control of the milk-supply, and if a regular veterinary inspection of all milk-producing cows were made obligatory, the incidence of tuberculosis in milk would be materially lessened. This has been proved over and over again in the boroughs and the few county districts where veterinary staffs are so employed. The final goal must, however, be the eradication of bovine tuberculosis from our herds, and a scheme for attempting this colossal task has already been drawn up by the National Veterinary Medical Association of Great Britain and Ireland.

I am, Sir, yours faithfully,

D. S. RABAGLIATI,
Chief Veterinary Officer, West Riding of
Yorkshire County Council.
Oct. 3rd, 1932.

To the Editor of THE LANCET

SIR,—Referring to the menace of the transference of bovine tuberculosis by cow's milk to humans, Dr. Carling states that "it would appear that there is no absolute safety anywhere." While this reference is true in relation to liquid milk, may I point out that a degree of protection, which for all practical purposes may be regarded as absolute, is obtained by the use of milk powder prepared by the improved Just-Hatmaker roller process. When this process is carried out under scientific supervision and control, the bacterial count per cubic centimetre is very low, usually under a maximum of 150, and the remaining flora are of no pathogenic significance. This protection against bovine tuberculosis is achieved without deterioration of vital properties, the loss of vitamin value, if any, being negligible, and this conclusion, drawn from biochemical feeding experiments on animals,[*] is generally confirmed by the experience of medical officers of health and pædiatricians in charge of infant welfare centres and the infant departments of hospitals.

As to the query raised about the safety of Grade A (T.T.) Milk for school-children, it is interesting to note that in recent years roller milk powder, flavoured with chocolate and sweetened with sugar is being used in hundreds of schools as the morning milk ration. This form of chocolate milk not only gives protection against infection, but is much cheaper than Grade A (T.T.) liquid milk, and is in a form to be conveniently served hot to the children during the winter season. In this relation also reconstituted roller milk powder has the advantage of giving a pin-head flocculent rennin curd in contradistinction to the solid curd of liquid milk, a property of great physiological importance in relation to mid-morning peptic digestion.

If properly prepared milk powders were universally adopted in lieu of liquid milk for infant and child dietary, the danger of milk-borne disease would be practically eliminated.

I am, Sir, yours faithfully,

Dulwich, Oct. 3rd, 1932. JOHN CAMPBELL, Ph.D.

ACUTE RETROPHARYNGEAL ABSCESS

To the Editor of THE LANCET

SIR,—Amongst the cases of acute pharyngeal abscess recorded in your last issue by Mr. N. Asherson is one in which the mistaken diagnosis of diphtheria was made. From an experience of 36 years' residence in fever hospitals I should say that this error is not uncommon. It is one which has long been recognised. The only clinical lecture I heard Dr. Hilton Fagge deliver—unfortunately he was soon afterwards laid aside by illness from hospital work—nearly fifty years ago, was on "croup," and I remember that he warned us that a post-pharyngeal abscess might give rise to symptoms of laryngeal obstruction and so be mistaken for diphtheria; (see also Fagge's "Principles and Practice of Medicine," 1st ed., 1886, i., 801). In these cases, as was found in Mr. Asherson's sixth case, the abscess is usually situated rather low down, but it can often be detected by digital exploration, a procedure which should never be neglected in cases of "croup" in which there is no exudate on the fauces or Koplik's spots in the mouth.

I am, Sir, yours faithfully,

Hampstead, Oct. 2nd, 1932. E. W. GOODALL.

To the Editor of THE LANCET

SIR,—Referring to Mr. N. Asherson's most interesting article in your last issue, may I recall an article which I published in your columns [1] 30 years ago containing an account of 17 cases. One of these patients was 3 years old, two were 2 years old, the rest were under 2. I think this age-incidence should be emphasised. The prognosis of the complaint is bad chiefly because its diagnosis is missed. Most of these patients do not have the good fortune to come into the hands of a laryngologist. In any case examination by laryngoscope is no easy matter in an infant and usually if the possibility of this complaint is appreciated in infants, and its symptomatology is recognised, laryngoscopic examination is not necessary for its diagnosis. As Mr. Asherson has pointed out, the disease may simulate laryngeal diphtheria. This possibility should have greater emphasis laid upon it. I hesitate nowadays to give an opinion as to the best route for opening the abscess, but seven infants on whom I operated through an external incision in the neck behind the posterior edge of the sternomastoid did well. This constituted all except one of the patients I treated personally. The one patient of my own series who died had Klebs-Löffler infection and acute broncho-pneumonia. The retropharyngeal swelling was a mere complication of these other conditions. From recollection I should say I did not find the operation difficult. There is this further point: that in infancy the most dangerous complication always to be feared is broncho-pneumonia.

I am, Sir, yours faithfully,

Mundesley, Oct. 3rd, 1932. S. VERE PEARSON.

PATHOGENESIS OF CAVITIES IN THE LUNGS

To the Editor of THE LANCET

SIR,—Most physicians and radiologists who have studied the subject now agree that annular shadows represent air-spaces in the lung, but I doubt whether they would agree with Dr. Macfie and Dr. Alexander that tubercle bacilli are always found in the sputum in such cases, or that annular shadows are always accompanied by shadows representing extensive tuberculosis in the lung. If extensive disease is present one cannot assume that the bacilli are derived from the structure represented by the annular shadow. Clinical and radiological observations suggest that there are two types of pulmonary cavities, one the well known, more or less chronic ulcerated cavity, usually loculated, the other a more or less recent spherical space represented by the typical annular shadow. In addition there may be intermediate forms. It seems to me probable that the second type consists of cavities opening out from a constricted bronchiole, or perhaps from one in which a valve has formed, and that these cavities are often distended by air under pressure.

Dr. Mitchell's theory that air passes through a perforation in a bronchus and forms an air-cyst in the interstitial tissues is a most ingenious one, and it accounts for most of the facts, but I would have expected the cyst to be mushroom-shaped or multiple rather than spherical and single. Dr. Morland's explanation of the way in which a high pressure could be produced in a cavity is, I think, reasonable, provided that the existence of a valve is granted. But one must be careful in arguing that the pressure produced during coughing can distend cavities, for that pressure, caused by contraction of the thorax, is exerted also on the surrounding lung tissue. I would suggest that the pressure exerted by the *other side of the chest* should be taken into consideration. The pressure on the sound side during coughing might well be higher than that on the affected side. Such an excess of pressure would be transmitted to the air in the bronchi of the affected side sooner than to the air-spaces (alveoli, &c.), and therefore might distend a commencing cavity. Repeated distensions, however small, would thus produce in the end a definite cavity even when no valve was present.

Personally I believe that the higher pressure produced by the opposite side of the thorax is the only reasonable explanation so far suggested which will account for certain puzzling phenomena such as the protrusion of the lung through a wound in the chest wall, and the occurrence of a high pressure in the (valvular) spontaneous pneumothorax.

I am, Sir, yours faithfully,

Harley-street, W., Oct. 1st, 1932. G. T. HEBERT.

To the Editor of THE LANCET

SIR,—In Dr. Sowerbutts's interesting case report the hypothesis is repeated that these shadows are due to air-cysts in the lung, but surely the evidence in support is not convincing. For (1) air escaping to the interstitial lung tissue would spread along the planes of least resistance, as does surgical emphysema. (2) Surgical emphysema of the lungs may be discovered at autopsy, and these air-cysts are not. (3) Large emphysematous bullæ are also readily detected at autopsy; even if collapsed the wall remains. (4) These annular shadows without any signs of cavity formation may persist for years with slight alterations and it is inconceivable that an air-cyst would so persist. From the moment of formation it would commence to absorb. (5) Under artificial pneumothorax treatment these shadows appear to form areas which do not readily collapse, indicating that at that point the pleura is adherent.

---

[1] THE LANCET, 1901, ii., 1117.

It would be idle to deny the possibility of more than one cause for such a radiographic appearance, but to me a pleural origin seems most in accord with he observed facts.—I am, Sir, yours faithfully,

Paignton, Oct. 4th, 1932.   ERNEST WARD.

RESPIRATORY EFFICIENCY TEST

To the Editor of THE LANCET

SIR,—The considerable interest aroused by the ecent observations of Dr. R. A. Young on the need or the measurement of respiratory efficiency and by he report of Dr. Alan Moncrieff who, in your issue of Sept. 24th, describes the results of a series of such tests on "the hospital population," requires, in view of this interest, a more strictly accurate representation of the views of Flack than has been given and generally assumed in Dr. Moncrieff's account. Flack, in the Milroy Lectures referred to, did not intend that the standards of efficiency as adopted by the Royal Air Force should be applied to the general civilian community. Instead, from a series of researches which included the study of a group of pilots who were stressed, unfit, and suffering from "breakdown in the bodily system" from various causes, he merely observed that "a similar condition of bodily inefficiency may be found among individuals who are deemed more or less normal members of the community." Surely this is not, as Dr. Moncrieff suggests, an "unjustifiable generalisation." The fact that evidence of similar inefficiency is discovered among the more or less normal patients attending Middlesex Hospital should come not as a surprise in terms of Air Force standards, but as a clear proof of Flack's contention.

Nevertheless, to those who have been long conversant with the work of Flack and more particularly concerned with the application of his tests, the report of Dr. Moncrieff's investigation has a refreshing appeal; but it must be remembered that these tests are too subjective in nature to give comparable results unless conducted under strictly standard conditions. Apart from a discussion of relative unfitness, one might offer this suggestion, that by retaining the principles, and by a modification of methods, Dr. Moncrieff might still find in these tests a solution to the clinical problems he had in view.   I am, Sir, yours faithfully,

H. W. CORNER, M.D.

Wimpole-street, W., Oct. 1st, 1932.

To the Editor of THE LANCET

SIR,—Dr. Moncrieff conveys the impression that the expiratory force and 40 mm. Hg tests are the main, if not the only, methods employed by the Royal Air Force to estimate respiratory efficiency. This is far from being the case. The vital capacity, calculated from height, weight, and chest measurements, and the breath-holding test, are at least of equal, if not greater, value as a gauge of respiratory efficiency than the test he quotes. Of the four tests connected with the estimation of respiratory efficiency, the expiratory force is probably of the least value, while the 40 mm. test is of more value in demonstrating the coördination between the cardiovascular and respiratory systems under stress than it has as a purely respiratory test.

It is unreasonable to expect that good results could be obtained from any efficiency tests without wholehearted coöperation of the subject concerned, especially in those requiring concentrated maximal effort to perform. For this reason I agree that the results obtained from out-patients cannot be satisfactorily compared with those obtained from Royal Air Force personnel. The essential purpose of the Royal Air Force efficiency tests is not directed so much towards gauging disordered function as towards the estimation of the relative degrees of efficiency among normal, healthy young adults. The average age of Dr. Moncrieff's cases was about 40—the limits being 17 to 70. Respiratory efficiency tests in general, such as those mentioned, are not applicable to elderly persons. The vital capacity may be quoted as a case in point. Calculated vital capacity from height, weight, and chest measurement as laid down in Air Publication 130, can only be applied up to the age of about 30, as increased weight and chest measurement occurring with increasing years would require a higher standard of vital capacity in an individual at 50 than at 20—which is absurd.

The tests employed by Dr. Moncrieff have never been considered applicable to severe cases of disordered respiratory function and might be dangerous if applied in this connexion; it is probable that in such cases a careful clinical examination in experienced hands is likely to prove of greater value than any of the existing tests of respiratory efficiency.

I am, Sir, yours faithfully,

H. A. TREADGOLD,
Consultant in Medicine, R.A.F.

Central Medical Establishment, Royal Air Force,
Clement's Inn, W.C., Oct. 3rd, 1932.

GASTRIC ACIDITY

To the Editor of THE LANCET

SIR,—In a series of articles on gastric acidity this year you have repeatedly drawn attention to recent investigations showing an intimate relation between the acid-base balance in the blood and the secretion of acid in the gastric juice; but you appear to be using these observations to support some new conception of gastric pathology. I admit I do not know what this new doctrine is; I do not always understand what you mean by "gastric acidity," and at times I am left with a haunting doubt as to whether you are clearly distinguishing between gastric juice and gastric contents; in one place in your first article (THE LANCET, 1932, i., 29) by a slip of the pen you definitely write gastric juice when you mean gastric contents. In the last article (August 13th, p. 352), however, you clearly invite us to believe that the acidity of the gastric contents is of little, if any, importance in the production of gastric symptoms. I cannot myself accept this invitation, but what puzzles me is where you find any connexion between these remarks in the opening paragraph and the very interesting experiments of Browne and Vineberg, which you discuss in the rest of your article. These experiments are entirely concerned with the control of the gastric secretion by alterations in the acid-base balance in the blood; but variations in gastric secretion have nothing whatever to do with the quite distinct problem of the effects produced in the stomach by variations in the acidity of the gastric contents. Although this point is really very obvious, it is frequently missed by those who write on gastric pathology. I do agree with your conclusion that we need a wide outlook, but I do not get on very fast if, keeping my eyes on the horizon, I stumble over the obstacles that lie at my feet. Will you help me by going back to that matter of the production of gastric symptoms with which you started, and explain how changes in the acid-base balance in the blood can play any part therein, if by hypothesis we deny any importance to changes in gastric acidity ?

If, indeed, in the treatment of peptic ulcer, oral administration of alkalis should have to be replaced by intravenous or subcutaneous injections, a prospect that you seem to regard rather light-heartedly, it will surely and rightly be hailed by the surgeons as *the last nail in the coffin of the medical treatment of* that condition.—I am, Sir, yours faithfully,

G. W. GOODHART.

Group Laboratory, Archway Hospital, N., Sept. 24th, 1932.

*** Our object in drawing attention to experimental work on the acid-base balance in the blood and the secretion of hydrochloric acid into the stomach was to point out that the secretion of HCl did not depend solely upon local changes in the stomach itself. It was not suggested that variations in acidity brought about by changes in the blood led to "gastric symptoms"; the intention was rather to indicate that the degree of acidity alone does not fully explain the symptoms of indigestion. Extremes are compatible with perfect health, and the investigations quoted do not suggest that symptoms are produced by changes in the plasma bicarbonate. It was not suggested that oral administration of alkalis in the treatment of peptic ulcer should be replaced by intravenous injections, and Balint's interesting observations were cited merely to show that the exact significance of gastric acidity in this disease is as yet far from fully understood and that experimental work bearing on it should not pass unnoticed. It is known for instance that, in cases of ulcer, gastric acidity may be higher after *alkali treatment* and cessation of symptoms than it was when symptoms were present, also that a high or low acidity may be found during the active stage without relation to the severity of the symptoms. —ED. L.

ERRATUM.—Dr. V. Rendall writes: "In a paper on Diathermy and Constipation, published in THE LANCET on August 6th last, an unlucky misprint occurs. In the comment on Case 5 the first six lines were a quotation from the findings at the New Lodge Clinic, while the last five lines were my observations. The quotation marks should have been placed, of course, at the end of the first six lines, and not at the end of the paragraph, and I regret the oversight which Dr. Hurst properly resents."

PUBLIC HEALTH SERVICES

Suggested Economies at Plymouth

THE Plymouth City Council recently appointed a special committee of inquiry into public health administration, and this committee has now issued a report recommending measures which will save more than £6000 a year. Plymouth employs 547 persons in its public health service, and the committee considers that several institutions are overstaffed. It suggests that one of the total staff to 1·6 patients is adequate in the Swilly Hospital for infectious disease, where the matron has a waiting-list of nurses who could be called upon in an epidemic. At Lee Mill small-pox hospital, at present quite unoccupied, there seems no reason to supply the caretaker and his wife with an assistant who is paid £120 a year. A consignment of beds and bedding for this institution is lying there unpacked, and the committee advises that it be taken into use elsewhere. At the City Hospital the staff ratio is 1 to 2·1 patients. For 456 patients in 17 wards the committee found 4 medical officers, 8 consultants, 134 nurses, a dispenser, a radiographer, a masseuse, and 103 others, and considers this excessive; the medical superintendent, however, declared that the place was under- rather than overstaffed. The average cost per patient per week was £2 5s. 5½d.; in the absence of figures from other institutions for comparison, the committee made no recommendation, but pointed out that at this hospital about 100 beds were usually vacant, while at the South Devon and East Cornwall (voluntary) Hospital there is a waiting-list of over 200; this led them to the view that more coördination between the voluntary and municipal undertakings, and avoidance of unnecessary duplication of plant and appliances were required. £600 a year could, it was held, be saved by appointing junior medical officers annually instead of permanent medical officers at £350 a year. The committee also advised the reinstitution of the pay-bed system, patients in these beds being attended by their private practitioners.

Considerable economy has already been effected by using ordinary raw milk for cooking purposes. Hitherto Grade A (T.T.) has been used at Didworthy Sanatorium, Swilly, and the City Hospital. At the City Hospital the saving effected by the change was £650, and at Swilly £156 per annum. The average weekly maintenance cost at Didworthy, 52s. 2·8d., is 9s. 5d. per week per patient above the average for such institutions. Here, again, reduction in staff is recommended—to a total staff of 25—and also reduction in the emoluments of some of the staff, a total economy of £1500 being held to be possible. The committee also strongly recommended that the new Mount Gold orthopædic hospital should only be staffed and equipped for one-half of its capacity, since not more than 50 patients belonging to the city were suitable for admission.

A saving of £1627 is suggested on the maternity and child welfare service, as the committee came to the conclusion that there was considerable overlapping with the voluntary organisations. It recommends the dismissal of one medical officer, four health visitors, one assistant investigation officer, and one clerk, and the abandonment of a proposed sixth centre. Since 1925 the staff has been increased by two medical officers, three health visitors, and a clerk, and the annual cost has risen from £5225 to £13,349. There are 18 sanitary inspectors, and the committee recommends that the number be reduced to 15, a saving of £1050 per annum, by letting vacancies remain unfilled when they occur. The town hall staff of ten should also, it thinks, be reviewed.

The committee emphasises the fact that its investigations have been by no means exhaustive and could profitably be continued. Its report is signed by four of the five members, and the fifth presents a minority report suggesting that the economies proposed are apparent rather than real, and will only shift the expense from one department to another. He disagrees with practically all the specific proposals made.

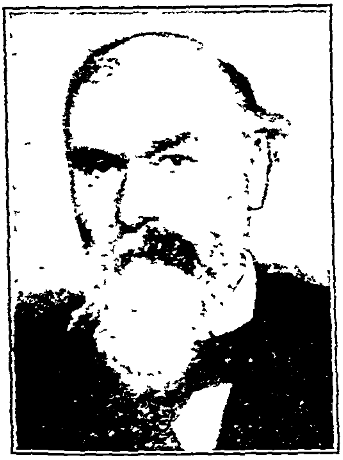
When the report was submitted to the Plymouth City Council the Labour members protested, and expressed unwillingness to accept any reductions in expenditure on public health. After prolonged discussion, both reports were referred to the Public Health and Maternity and Child Welfare Committees.

OBITUARY

WILLIAM STIRLING, M.D., D.Sc. Edin., LL.D. Glasg.

Prof. Stirling's death on Oct. 1st at his home in ictoria Park. Manchester, ends a long life of rodigious activity in the service of medicine.

William Stirling was the son of Francis Stirling nd Isabella Crawford, of Grangemouth, Stirlingshire, here he was born in January, 1851, and naturally e was educated at the Dollar Academy, going on o Edinburgh University where he graduated in cience in 1870 and in medicine in 1875, each time ith first-class honours. He took all the scholarhips and prizes for which he was eligible, and at he same time made mental notes of the habits and peculiarities of his teachers, a faculty which revealed his bent as a student of men. Among the teachers under whose influence he came, as he himself has told us, was J. H. Balfour, the dryness of whose teaching earned him the world-wide synonym of "woody fibre"; G. J. Allman, a congenial Irishman, whose knowledge and appreciation of invertebrate fauna led him to tell of the amœba "with its sad and doleful cry" and its ill-equipped digestive arrangements; Lyon Playfair, a pupil and friend of Liebig, who with the help of James Dewar introduced the student to the chemistry of foods and dietaries; William Turner, bold, decisive, precise, and superbly audible as a lecturer and a prince of demonstrators; J. Hughes Bennett, like a modern Justinian, laying down the law in his institutes of medicine, and furious with Virchow who had dared to substitute leukæmia for his own term leucocythæmia; James Spence, an excellent operator and careful surgeon but not an inspiring speaker, whose dissections of the injected blood-vessels of the foot still bear witness to his manipulative skill; Robert Christison, whose course of 100 lectures carried his hearers from Tinevelly senna to inunction of the thyroid by a mercurial salve, and his own imminent death from swallowing calabar bean averted only by the immediate swallowing of his shaving-water; Douglas Maclagan, the bard of the medical faculty, who combined medical jurisprudence and the teaching of public health; W. R. Sanders, whose teaching of pathology was largely pathological anatomy, Paget at home and Rokitansky in Vienna being names to conjure with; the erudite Thomas Laycock, who gave daily disquisitions on "omitted chapters" in medicine with a style all his own. J. Y. Simpson had already reached his zenith and was stricken with angina pectoris; his nephew, Alexander, who followed him, treating his subject balanced by the physiology and pathology of the modern German school. On the clinical side Bennett, with his didactic and precise method of examining patients at the bedside whatever the alleged diagnosis; "where do you feel pain?" was the first and invariable question, and woe to the student who omitted it. James Syme, of wonderful dexterity, whose lessons taught so pithily and forcibly by demonstrations were never forgotten; and finally, Joseph Lister, transferred from Glasgow to succeed his father-in-law, who applied modern physiology and pathology to the infant bacteriology, and who demonstrated to astonished fourth-year students the blood clot lying in a compound fracture without becoming septic.



PROF. STIRLING

These were Stirling's teachers at Edinburgh, and we draw on his own reminiscences to describe them. Later he went to work with Karl Ludwig at Leipzig and Ranvier in Paris, returning to demonstrate for W. Rutherford at Edinburgh until in 1877 he was appointed to the chair of the institutes of medicine at Aberdeen. Nine years later, on the retirement of Arthur Gamgee, he was called to Owens College, Manchester, as Brackenbury professor of physiology and histology, and for 33 years he represented physiology at the College and the University. It was largely owing to his energy that the great block of laboratories arose as an annex to the medical school. As dean of the faculty of medicine from 1902–13, his administrative ability found full scope. So successful was he as organiser and teacher that it is rather in these capacities than for original work that Stirling will be remembered. He possessed a commanding figure and personality which impressed his students, both at lectures and in the laboratory, and he knew their needs. Before his transference to Manchester he had translated Leonhard Landois's text-book of human physiology, with so many emendations and additions that it became in his hands largely a new work. The book was unique in its attention to the practical bearings of physiology on medicine and surgery, making it possible for the student on entering the wards of the hospital to understand disease as a modification and perversion of normal processes. This result was actually achieved by Stirling in the early years of his professorship, and a large share of the success of the medical school of that epoch may be rightly allotted to Stirling's groundwork, none the less effective in that his teaching was frank at times almost to the degree of coarseness. A few years after reaching Manchester he brought out two smaller manuals, one on practical histology, the other covering chemical and experimental physiology, which became the guides of students in many medical schools. Stirling was happy in his publisher, Charles Griffin and Co., who were lavish in allotment of space and illustrations. His other important writing was a later study, entitled "Some Apostles of Physiology," in which he set out their contributions to the advancement of the healing art as well as to the prevention of disease. His knowledge of his colleagues was world-wide, for he visited every international physiological congress and had first-hand knowledge of nearly all the continental schools. Stirling retired from the chair of physiology in 1919, but continued to make use of his vast store of information in papers of historical character and other ways.

So completely indeed had he retired that few of the present generation of students knew him. One of his old students writes: "While Stirling did not perhaps go as far in research as was expected of him, he did much in coördinating our knowledge and going back to that matter of the production of gastric symptoms with which you started, and explain how changes in the acid-base balance in the blood can play any part therein, if by hypothesis we deny any importance to changes in gastric acidity?

If, indeed, in the treatment of peptic ulcer, oral administration of alkalis should have to be replaced by intravenous or subcutaneous injections, a prospect that you seem to regard rather light-heartedly, it will surely and rightly be hailed by the surgeons as the last nail in the coffin of the medical treatment of that condition.—I am, Sir, yours faithfully,

PUBLIC HEALTH SERVICES

Suggested Economies at Plymouth

THE Plymouth City Council recently appointed a special committee of inquiry into public health administration, and this committee has now issued a report recommending measures which will save more than £6000 a year. Plymouth employs 547 persons in its public health service, and the committee considers that several institutions are overstaffed. It suggests that one of the total staff to 1·6 patients is adequate in the Swilly Hospital for infectious disease, where the matron has a waiting-list of nurses who could be called upon in an epidemic. At Lee Mill small-pox hospital, at present quite unoccupied, there seems no reason to supply the caretaker and his wife with an assistant who is paid £120 a year. A consignment of beds and bedding for this institution is lying there unpacked, and the committee advises that it be taken into use elsewhere. At the City Hospital the staff ratio is 1 to 2·1 patients. For 456 patients in 17 wards the committee found 4 medical officers, 8 consultants, 134 nurses, a dispenser, a radiographer, a masseuse, and 103 others, and considers this excessive; the medical superintendent, however, declared that the place was under- rather than overstaffed. The average cost per patient per week was £2 *5s. 5½d.*; in the absence of figures from other institutions for comparison, the committee made no recommendation, but pointed out that at this hospital about 100 beds were usually vacant, while at the South Devon and East Cornwall (voluntary) Hospital there is a waiting-list of over 200; this led them to the view that more coördination between the voluntary and municipal undertakings, and avoidance of unnecessary duplication of plant and appliances were required. £600 a year could, it was held, be saved by appointing junior medical officers annually instead of permanent medical officers at £350 a year. The committee also advised the reinstitution of the pay-bed system, patients in these beds being attended by their private practitioners.

Considerable economy has already been effected by using ordinary raw milk for cooking purposes. Hitherto Grade A (T.T.) has been used at Didworthy Sanatorium, Swilly, and the City Hospital. At the City Hospital the saving effected by the change was £650, and at Swilly £156 per annum. The average weekly maintenance cost at Didworthy, *52s. 2·8d.*, is *9s. 5d.* per week per patient above the average for such institutions. Here, again, reduction in staff is recommended—to a total staff of 25—and also reduction in the emoluments of some of the staff, a total economy of £1500 being held to be possible. The committee also strongly recommended that the new Mount Gold orthopædic hospital should only be staffed and equipped for one-half of its capacity, since not more than 50 patients belonging to the city were suitable for admission.

A saving of £1627 is suggested on the maternity and child welfare service, as the committee came to the conclusion that there was considerable overlapping with the voluntary organisations. It recommends the dismissal of one medical officer, four health visitors, one assistant investigation officer, and one clerk, and the abandonment of a proposed sixth centre. Since 1925 the staff has been increased by two medical officers, three health visitors, and a clerk, and the annual cost has risen from £5225 to £13,349. There are 18 sanitary inspectors, and the committee recommends that the number be reduced to 15, a saving of £1050 per annum, by letting vacancies remain unfilled when they occur. The town hall staff of ten should also, it thinks, be reviewed.

The committee emphasises the fact that its investigations have been by no means exhaustive and could profitably be continued. Its report is signed by four of the five members, and the fifth presents a minority report suggesting that the economies proposed are apparent rather than real, and will only shift the expense from one department to another. He disagrees with practically all the specific proposals made.

When the report was submitted to the Plymouth City Council the Labour members protested, and expressed unwillingness to accept any reductions in expenditure on public health. After prolonged discussion, both reports were referred to the Public Health and Maternity and Child Welfare Committees.

envelopes. In most instances the difficulty has arisen in dealing with the records of a practice in which one practitioner has succeeded another, or a change has been made in the partners of a firm. It is obviously desirable that the regional medical staff should be able readily to identify the name of the practitioner who is in fact responsible for keeping the records, and the Ministry has asked insurance committees to take steps to ensure that all records bear the correct particulars.

Hypnotism in the Treatment of Asthma

An insurance practitioner who performs a service which he considers outside the scope of medical benefit as defined in the terms of service may charge the insured person for the service if within seven days he notifies the insurance committee on form G.P. 45 whether it was "urgent" (this term has recently been altered to "an emergency") and gives proof that he did possess special skill beyond that ordinarily possessed by a general practitioner. The charge is allowed to stand if the insurance and local medical committees agree that everything is in order. In a case which came up at Manchester recently the details of the "operation" given were:

1. Patient has for years suffered from asthma which has lately become intolerable.
2. Suggestion under hypnotism, for which Mr. E is a suitable case, being extremely susceptible to hypnotism.
3. Not urgent, but it is performed in desperation as all the usual remedies have failed in his case.

The local medical committee stated that in their opinion the "operation" was not within the scope of an insurance practitioner's obligation, and that the practitioner did possess the necessary skill. This case is similar to the London cases, in which psychotherapy was used to cure a painful neck and some other neurosis, and which are awaiting the result of appeal to the Ministry. The London local medical committee (with some dissentients) decided that the service was beyond the scope of medical benefit, the London insurance committee disagreed and decided to get a Ministerial ruling; in Manchester however both committees agreed on the point, so that unless the Ministry upsets this decision hypnotism for the treatment of asthma may be charged for when treating an insured person.

Certification without Seeing the Patient

Another medical service case heard at Manchester raises the question of procedure when complaints are received against insurance doctors.

> A communication dated June 7th was received from an insured person in which he stated he was under domiciliary treatment and had been under his doctor for 18 years, but that he was last visited on April 22nd and since then his doctor had been taken ill and had not visited him; also that his daughter had attended at the doctor's surgery every week for his certificates which had been given without the doctor seeing him, and he asked what was the best course to take. The clerk to the insurance committee reported that a copy of this communication was taken to the doctor by an officer of the committee with a letter pointing out that it was important the patient should receive medical attendance from him personally or by deputy without further delay, and the doctor was found to be confined to his bedroom and unable to visit the patient that day, but he promised to visit him on the following afternoon and said that in his opinion the patient could not have urgently required attention. The patient was also visited and was told that the doctor would visit him on the following day, and upon the man expressing his desire to transfer to another doctor he was informed that he had a card which enabled him to do so immediately, and the procedure for change of doctor was explained. The doctor's reply to the committee's request for his observations upon the patient's statements was also submitted, in which he stated that sickness of a severe nature had completely disabled him for some time, but that from the experience gained during the 18 years the patient had been under his care he was of opinion that visiting was unnecessary, but he regretted that his deputy had not been instructed to visit the case and gave an assurance that a repetition would be avoided. A copy of the doctor's statements was sent to the patient with an inquiry if his letter was intended to be a complaint for investigation by the medical service subcommittee, but no reply had been received to this letter nor to a further communication which had been sent, and he had not transferred to another doctor. A resolution was adopted that the correspondence submitted should be referred to the chairman, vice-chairman, and two medical members of the committee, with power to deal therewith.

Here the chief offence lay in the giving of certificates without seeing the patient. There was a somewhat striking case of a similar nature some little time ago in London, where the doctor gave certificates of incapacity, dating several of these back, and it was eventually proved that at the time the certificates of incapacity were given the insured person was in Wormwood Scrubs for some criminal offence, although the doctor thought he was still in the hospital to which he had been sent. The usual procedure in such cases is to write to the doctor and ask his observation on the statements, and in most cases to require attendance of the doctor and complainant, who in certification cases is often the representative of the approved society, before the medical service subcommittee, who then hear the evidence and decide on the penalty. The hearing may last an hour, to say nothing of time taken in getting to and from the place of hearing, and there is often for the doctor the mental agony of the unknown procedure, "What will they say? . . What will they do?" It is an irksome and invidious procedure for a doctor who has quite honestly, although against regulations, tried to assist the insured person to get his sickness benefit. The doctor is met with "I shall not have anything to live on if I don't get my certificate," or "I forgot to ask the hospital doctor, so as you know he is in hospital will you give me a certificate," or "The agent wants a certificate, and said I was to ask his doctor for one." Out of the kindness of his heart and forgetting the wording *I have examined you on the undermentioned date,* he gives a certificate, which is in effect a cheque on the approved society, and breaks the regulation. On discovery the above procedure then usually begins. Manchester however appears to have adopted the unusual but much more humane course of sending an officer to interview both doctor and patient, to both of whom the position is carefully explained, and eventually the chairman, vice-chairman, and two medical members of the committee deal with the matter. The doctor is put wise without wasting his time and being made to feel like a naughty boy. The patient gets what he wants, namely, a change of doctor, and all is settled without ill-feeling on either side. No doubt for the bad case there should be some sterner method. The whole question of procedure at medical service cases is likely to come up at the annual conference of insurance committees to be held next week at Buxton.

QUEEN MARY'S HOSPITAL, ROEHAMPTON.—The annual report of this hospital for sailors, soldiers, and airmen who lost limbs in the late war, which has now completed its seventeenth year, contains a review of the work done during its existence. Of slightly more than 41,000 men who lost limbs in the war, 24,427 were admitted up to June 30th last for the supply of their first limb, and in many cases also for their second. There have been 35,983 attendances for repairs and renewals, and 103,919 cases have been dealt with through the post. The London County Council is now sending civilian cases from hospitals under its control on conditions similar to those on which cases from the railway companies and other public bodies are admitted.

was without rival as a teacher. The pains he took to illustrate his teaching by lantern and microscope slides was beyond all praise. As a popular lecturer too in subjects relating to medicine he was in great request. His lecture to the British Association in 1915 on curiosities and defects of sight, illustrated by a booklet full of pictures, may be mentioned as an instance of his extraordinary thoroughness. He was lavish both in money and in time when he had agreed to give a lecture. His book on Apostles of Physiology, written in coöperation with Walter Whitehead, is now a treasure for the booklover."

Prof. Stirling married Elisabeth Ferguson Crawford and leaves two daughters and two sons, one of whom is registrar to the Advocate-general, the other a leading consultant in ophthalmology in Manchester. The photograph which we reproduce appeared on the cover of a popular lecture given a few years ago. He had no studio portrait taken but there are many excellent contemporary caricatures of the impression he gave as a teacher, the best being one entitled "A Vacation Nightmare" done by Mr. H. T. Lamb, the war artist, when he was a medical student.

PANEL AND CONTRACT PRACTICE

Approved Society Surpluses

At the twentieth annual conference of the Scottish Association of Insurance Committees, Mr. John Hill, president, dealt with the anomalies of the third valuation. This was, he said, expected to be a critical valuation. The enormous surpluses of the first and the large surpluses of the second valuation were not anticipated. The forecast had again been more or less falsified; for some societies have large surpluses and others small or none at all. Mr. Hill suggested that the segregation of large numbers of insured persons engaged in hazardous occupations to a society of their own had thrown an almost impossible burden upon those societies, and that the other societies were relieved of liabilities that might well have been theirs to share. They knew of well-known societies that, with increasing sickness and serious loss of contribution income, were going to experience desperate times to make ends meet. He did not advocate pooling of all surpluses. But did anyone think there could be a continuance within the Insurance Acts of societies with surplus money they did not know what to do with and, on the other hand, societies at their wits' end to know how to keep solvent? A continuance of these conditions spelt disaster. He was prepared, he said, to take 50 per cent. of all surpluses, and with the funds provided he would first of all make dental benefit statutory. He would cut out all other extra benefits and establish what to his mind was the most urgent need of the insured person—namely, a specialist and consultant service, together with up-to-date diagnostic facilities for the panel practitioner and his patients. The remainder of the fund he would conserve to provide a safeguard to every insured person that their benefits under the Act were sure. What they looked upon as abnormal sickness experience was probably going to be the normal experience for many years to come.

Miss Ritson, controller of insurance for the department of health, pointed out that, according to the International Labour Office, the difficulties in Scotland were common to most countries—lowered contribution income, unemployment, high sickness and disablement rates. As to contributions, there was still in Scotland a very considerable residual burden. The greatest fear, however, was that the sickness and disablement claims were rising. That year they had experienced in Scotland a rise that was frankly disconcerting. The situation in 1932 promised not to be so good as in 1931 and 1930. In Glasgow there had been a 5 per cent. rise in the number of illnesses over 1931. They could not relax their efforts if the new N.H.I. Act was to bring prosperity. A very special responsibility fell on medical practitioners for granting prescriptions and certificates. The causes of heavy incidence in certification would have to be probed, especially as that heavy incidence appeared to be peculiar to certain practices.

Chemists' Remuneration

There has been some evidence of determination on the part of panel chemists to insist that the clause in their agreement, which the Minister of Health wishes to remove in the 1933 contracts, shall be retained. The clause is as follows:

> A chemist shall not give promise or offer to any person any gift or reward (whether by way of a share of or dividend on the profits of the business or by way of discount or rebate or otherwise) as an inducement to or in consideration of his presenting an order for drugs or appliances on a prescription form provided by an insurance committee.

Retail chemists think the removal of this clause will be detrimental to the efficiency of the dispensing service, and that prescriptions would be dispensed on a commercial rather than professional basis as a result of its deletion. The opinion of coöperative societies, which feel themselves to be attacked by the presence of this clause in their contract, is that they should have the right to dispose of their profits in any way they choose without outside control. A conference, representing 12,000 chemists under contract for insurance dispensing, held in London on Sept. 28th, accepted the financial terms offered by the Ministry, provided that the clause in question is retained. Failing agreement they ask for the matter to be submitted to independent arbitration.

Compensation for an Eye

It was pointed out in these columns recently (p. 705) that a workman is not necessarily entitled to compensation from his employer simply because he has lost an eye during the course of his employment. The Council of British Ophthalmologists, in a report on compensations for eye injuries, state they are of opinion that the Workmen's Compensation Acts should be amended in such a way as to secure to the injured workman, in addition to the benefits at present allowed in respect of loss of earning power, a lump-sum payment to compensate for permanent loss of function and/or disfigurement. The report adds that this principle is already embodied in certain schemes operated by private firms in this country and the principle of lump-sum payments for partial or total loss of vision and other ocular disabilities was recognised in the regulations for the granting of war pensions. It was thought this would result in less delay in settlement of claims, less subsequent demoralisation with deterioration of eyesight and health, and also less litigation.

Practitioners' Names

A circular letter from the Ministry of Health calls attention to the difficulty sometimes experienced by regional medical officers in their inspection of medical records, owing to the inaccuracy of the names on the issue of a century ago a lively complaint of the way in which the hospital staff wasted the time of the students—Mr. Guthrie only being punctual in his attendance; and regretted the absence from our present-day columns of such homely and libellous details. Sir Holburt, in reply, attributed his priority in speaking to the fact that he had once been addressed as "The Very Rev. the Dean of St. Bartholomew's Hospital." He spoke of *improvements in the curriculum* of medical education, to be suggested by a committee appointed to consolidate, improve, and unify medical education in the metropolis, where, he said, the problem was of peculiar difficulty owing to the requirements of the various examining bodies. Referring to the British Pharmacopœia issued that day, he continued to cherish a hope for the issue of a basic pharmacopœia for the benefit of the medical student. Dr. Foxley Norris told a story about a Scottish ferry with an exhaustive tariff for different kinds of vehicles and passengers, which broke down when a menagerie came that way; if you fully retail the list of guests you may, he said, leave out the elephants. He was himself the great grandson of Pott's fracture, and as four generations of forbears on his mother's side hung on the walls of the College of Surgeons he did not feel a total stranger at the gathering. Incidentally he revealed that the chairman, as chieftain of the Macgillivrays, should have been wearing the kilt. The toast of "The Chairman" was proposed by Dr. Thompson Barron, who told stories of student days which inculpated himself as much as Dr. Watson, who rounded on him later with the outspokeness of one who had lived a long while in the West Riding. At the conclusion of his lively reminiscences, tribute was paid to the team-work of the dinner secretaries, Dr. W. Ernest Lloyd and Dr. Peter Kerley.

St. Bartholomew's Hospital

Prof. G. E. Gask presided at the old students' dinner on Oct. 3rd, when there was a very large attendance of old Bart.'s men from all parts of the country, and an unusual number of distinguished guests. In proposing "The Hospital and Medical College," Mr. Gask made the traditional survey of past, present, and future. He referred with feeling to a number of old students who had maintained the traditions of the school—Ross, Andrewes, Calvert, Legge, and many others. To the memory of Nigel Cohen, a present student killed in an aeroplane crash, a little garden had been dedicated in the hospital square. Dealing with the living, he congratulated the treasurer, Lord Stanmore, on becoming a member of the Privy Council, Sir Holburt Waring and Prof. Langdon Brown on appointment to high office. No outstanding event, he said, had occurred during the year, but the new surgical block continued to approve itself. The governors' plan of continuous steady development went on, and hope still burned that the whole hospital would gradually be rebuilt. In the medical school last year there were 126 full students; this year far more, 90 per cent. of them university graduates or undergraduates. There had been many successes in the athletic field, including a nearly successful attempt to swim the Channel; next year, with a bit of luck, we might hope to see a Bart.'s man at the summit of Mount Everest. The present-day student, he was satisfied, showed no lack of initiative, but medical education had not kept pace with the golden age of medicine in which we were living. The teaching staff numbered 102 individuals; various departments were bursting for room and the school must expand. Now came the opportunity, almost too good to be true, of transferring the whole college to the Charterhouse site, an ideal in support of which the teaching staff had put up the sum of £12,000, almost the equivalent of a whole year's emolument. The proposed expansion was not just for the honour and glory of Bart.'s; the medical schools of London, he felt, must increasingly unite, amalgamate, and coöperate. The scheme was to promote British medicine in its biggest and widest sense. Mr. Reginald Vick, as warden of the residential college, proposed "The Guests," regretting that the Medical College could offer the boundlessly hospitable city fathers in these hard times nothing more than a nourishing and wholesome repast. He welcomed the presence of the treasurer and almoners, the heads of the Medical Services, the city dignitaries, among them Sir George Wilkinson who that morning had received the accolade, the masters of four city of companies and of the Apothecaries, the Regius professor medicine at Oxford, the quondam Bishop of Chester, the high master of St. Paul's School, the senior surgeons of Guy's and St. Thomas's, and especially Sir Henry Newland, president of the Royal Australasian College of Surgeons. Sir Farquhar Buzzard, on behalf of the guests, returned thanks for its good cheer to a medical school which, he admitted, was one of the most progressive on the north side of the river. In the course of the evening several old students agreeably entertained the company, Dr. Nicholson with a song, Mr. Richards with a violin solo, and Dr. Cullinan with sleight of hand.

Middlesex Hospital

Mr. Eric Pearce Gould, who took the chair at the annual dinner at the Savoy Hotel on Oct. 4th, said that even the economies of the past year had had their silver lining; for instance the setting-aside of rooms for paying patients was providing experience which would be useful when the Woolavington block was opened next year. They had also had a golden lining; for the suggestion that research should be curtailed had led Mr. S. A. Courtauld to give £20,000 to prevent this happening. As regards the achievements of the year, the students (though not the nurses) were still hiding their athletic prowess under a bushel; however, in another branch, the hospital had doubled its representation on the council of the Royal College of Surgeons, and by the addition of Mr. Gordon-Taylor and Mr. A. E. Webb-Johnson had contributed not only surgical distinction but administrative ability. But the greatest changes of the past twelve months were structural. The steel framework of the east wing was now in position and the work of casing it had begun. The money for the steel and most of the casing was available, but a considerable further sum would be required for completion and equipment, and an appeal to the public would be made within a few days. If it was said that this was not the time for expansion of the voluntary hospitals, his answer was that these hospitals were the standard by which all hospitals must be judged, and they must continue to lead. In two years' time, if all went well, the building would be complete. Mr. S. A. Courtauld, chairman of the council of the medical school, mentioned that Middlesex men (Dr. J. G. Scadding and Mr. P. B. Ascroft) had won gold medals in the M.D. and the M.S. examinations of the University of London. The entrance to the school in the past year had been far the highest, certainly since the war, and with the hope of better times the hospital could look forward confidently to its centenary in 1934. Dr. Izod Bennett, dean of the medical school, said that his chief task was to bring about coöperation; but what was called team-work, if unintelligently applied, could do as much harm as it could do good in other circumstances—a statement which he supported by a moving story. Mr. H. W. Salmon, with the licence of a senior Broderip scholar, was fluently shocking; but Mr. Webb-Johnson in proposing The Guests soon sobered his hearers by recalling the great benefactions received from some of them. His toast was coupled with the name of Major J. J. Astor, M.P., and he told for the first time how Major Astor had come to the aid of the medical school in its difficulties. The chair of physiology had an endowment worth over £32,000. This was the anonymous gift of Major Astor twelve years ago, and application was now being made to the University of London to have the professorship linked with his name. Major Astor in his reply said that organisations like the Middlesex were characterised by sympathy, efficiency, and cheerfulness. Those who work in hospitals had these qualities so highly developed that he wondered why they could not eliminate in other people, perhaps by a simple operation, such qualities as mistrust and pessimism: at any rate, he said, they had done this to their guests to night. Dr. G. E. S. Ward spoke of the chairman's services to the Hospital, and those of his father before him, and Mr. Pearce Gould's health was drunk with musical honours.

Leeds University

At recent examinations the following candidates were successful:—

M.D.

G. F. Bramley (with distinction) and R. C. Hanson.

FINAL EXAMINATION FOR M.B., CH.B.

Part I.—G. Cohda, A. Cohen, P. Crann, T. A. Divine, R. W. Rutter, T. Simpson, A. Smith, J. F. Warin, and Lydia A. Wilson.

Part II.—B. W. A. Fleming, J. J. Fry, J. S. Gourlay, E. James, J. Littlewood, R. Raines, M. Rosental, S. Strasburg, and J. Taylor.

Part III.—M. Rosental (second-class honours), B. W. A. Fleming, J. J. Fry, J. S. Gourlay, F. R. W. Hemsley, E. A. James, E. James, F. C. Leach, J. Littlewood, R. Raines, S. Strasburg, and J. Taylor.

Old Regulations.—M. A. Rashid.

FINAL EXAMINATION FOR L.D.S.

C. L. Davidson, J. D. Sykes, F. Wilcock, and G. O. Wood.

The William Hey Medal and the West Riding Panel Practitioners' Prize have been awarded to E. Gledhill.

Chadwick Lectures

On Thursday, Oct. 20th, Sir Humphry Rolleston will give a lecture on the Pioneers and Progress of Preventive Medicine. It will be delivered in the theatre of the Royal United Services Institution, Whitehall, London, at 5.15 P.M. Particulars of subsequent lectures may be had from the secretary of the Chadwick Trust, 204, Abbey House, Westminster.

MEDICAL NEWS

HOSPITAL DINNERS

St. Mary's Hospital

Sir Joseph Skevington, senior surgeon to the King Edward VII. Hospital, Windsor, presided over the annual dinner of the medical school, held at the Trocadero Restaurant on Sept. 30th. Proposing the first toast, Lieut.-Colonel H. E. Verey, chairman of the hospital board, said that the great event of the year had of course been the rebuilding of the medical school and pathological institute, which would, he hoped, be finished and occupied this time next year. The policy of buying the island site in 1927 had been more than justified, and though the hospital was still feeling severely the financial sacrifice then required, he hoped that as soon as the present building had been paid for a united effort would be made to complete the new nurses' home. The expansion of St. Mary's depended on this project and the need was urgent, especially in view of the powers now given to public authorities to construct State-supported hospitals. The policy of St. Mary's had been, wherever possible, to secure the coöperation of the local authorities so as to retain all the public and semi-public medical departments which were essential if the medical school was to provide the complete curriculum on one and the same premises. By this policy they had succeeded in retaining the tuberculosis dispensary, the treatment of L.C.C. school-children, and a great number of other public health services, and next April a maternity ward was to be opened whose cost of maintenance would be met by the Paddington borough council. Thus, without any maintenance cost to the hospital, enough clinical material would be provided for the instruction of students. He felt that the treatment of the sick and the advancement of science depended on the freedom, elasticity, individuality, flexibility, initiative, and responsiveness which in this country had always been the outcome of voluntary work. After referring to the death of Mr. Prideaux, chairman of the board of management for more than eleven years, and Mr. Stower, a vice-chairman—from both of whom the hospital would receive large legacies—Colonel Verey went on to speak of the appeal being made in connexion with the centenary of Lewis Carroll. Some £3000 had already been contributed towards the £10,000 that was needed to establish a model children's ward at St. Mary's, and no fitter memorial could be found for a man who had loved and amused children, and whose nephew, Prof. B. J. Collingwood, was now a member of the hospital staff.—Dr. C. M. Wilson, dean of the medical school, spoke of the lead which St. Mary's had given in arranging post-graduate courses for old students. With an entry this year of 60, and with the new buildings up, it might be imagined that the work of advancement was over; but life, he insisted, was movement, and without further effort their plans could not be realised.—Dr. Wilfred Harris, in proposing the health of the chairman, was limited by a ruling that speeches should be very short; but his brief remarks reflected the goodwill of the company, and Sir Joseph Skevington expressed his thanks.

St. George's Hospital

The annual dinner of the medical school was held at the Hyde Park Hotel on Oct. 1st. The chair was taken by Sir Crisp English, senior surgeon to the hospital, and about 150 past and present St. George's men attended. Among the guests were Lord Greville, treasurer of the hospital, Captain Evan Wallace, M.P., Sir Henry Newland, of Adelaide, and Dr. G. C. Anderson, medical secretary of the British Medical Association. Captain Wallace, in proposing the toast of the Medical School said that he and his colleagues of the house committee were very proud of their school, and wished that, with the help of an enlightened public, they could provide a more modern and efficient building for it to work in. In the course of a witty speech he reminded the medical profession that, although its rewards were precarious, it had the satisfaction of being universally respected and honoured, whereas his own profession was almost universally despised and made fun of. Dr. Anthony Feiling, dean of the medical school, who responded, said that the school was in an exceptionally healthy state, apart from its actual bricks and mortar. Although they might dream of tessellated pavements and marble swimming-baths, excellent work was being done in the old surroundings. The examination results in the past year had been above the average. Dr. Feiling also referred to the death of two distinguished St. George's men during the past year—Sir William Bennett and Dr. F. G. Penrose. Mr. P. T. Cooper, who also responded for the school, expressed the point of view of the students and those recently qualified. He managed to make amusing observations at the expense of many members of the staff. Mr. Ivor Back, in proposing the health of the Chairman, spoke of Sir Crisp's approaching retirement from the active staff. It was common knowledge that the chairman had been successful in his profession, and he had heard it said that he had had a lot of luck. Success in the medical profession, however, was not due to luck. The goddess of fortune would pay a man no attention unless she perceived the qualities that make for greatness—namely, kindness, tolerance, and a knowledge of human nature, allied to a first-class technical skill and a sound clinical instinct. All of these things the chairman possessed in an extraordinary degree. Further, during his life on the active staff, he had been a great friend and a great servant of the hospital which gave him his medical birth and nurture, and the whole of his ardent spirit had been devoted to the "Corner." They wished him many years of health and vigour in which to conquer fresh worlds and pastures new. Sir Crisp English expressed his gratitude to the speakers and to all his friends present. He took the opportunity of thanking those who had helped him during his life at the hospital—his house surgeons, the sisters and nurses, the lay committee members, the treasurer, the secretary, and the porters. He would always retain his love for the hospital and would always resist changes which might tend to destroy its individuality.

Charing Cross Hospital

In the absence of Dr. William Hunter, Mr. C. Carter Braine presided over the annual dinner of the medical school at Gatti's Restaurant on Oct. 1st. He had previously occupied the chair, he said, in 1894, and he felt that once was enough. His experience went back over 50 of these dinners, and he recalled old days at the Holborn Restaurant and elsewhere, when the programme always included two songs—The Laird o' Cockpen, from Cantlie, and Ten Thousand Miles Away. What a contrast there was between the hospital when he entered it and the hospital of to-day! Then it was dull, dismal, and badly ventilated; there were rings screwed in the floors of the wards—for the reduction of dislocations. Then came antiseptic methods. At 9 P.M. the night before an operation the carbolic spray was started in the theatre, and when the surgeon began work at 9 A.M. next day the atmosphere was that of a London fog, so that subsequent carboluria was common. There was only one operating day. The patients were admitted two or three days before the operation, to get acclimatised. They often did get acclimatised—and walked out. Mr. Braine described himself as the last of the septic house surgeons.—Mr. Crook, dean of the medical school, began by acknowledging the kindly efforts of laymen to leave their bodies—some with appendix intact—for dissection; but rapidly passed on to the more congenial subject of football. The school, he said, had beaten University College Hospital at rugger; "and in many ways," he added wistfully, "we very nearly beat George's." Mr. Bright Banister recalled the chairman's power to induce perfect anæsthesia with a smell of indiarubber and a powerful personality. In proposing his health he spoke in very warm terms of Mr. Carter Braine's association with the hospital, in which he had always shown himself an honour to the profession. By way of reply the chairman said that he had not expected to enjoy his evening, but he had certainly done so; and he hoped that everyone else had done the same. The general air of the gathering, and the applause greeting the songs of Dr. S. Taylor Harris and Mr. Frank Hart, left no doubt that this hope was fully realised.

Westminster Hospital

Past and present members of the medical school sat down to dinner at Grosvenor House, Park-lane, on Oct. 1st, when the chair was taken by Dr. R. Nimmo Watson, honorary physician to the Royal Bath Hospital at Harrogate. After an excellent repast the toast of "Hospital and Medical School" was proposed by Mr. Arthur Evans, surgeon to the hospital, who recounted the doings of the past twelvemonth, with particular reference to the development of new laboratories under Dr. R. J. V. Pulvertaft. He welcomed the new out-patient clinic for early mental cases which was breaking fresh ground, and foreshadowed not only prosperity but continued expansion for the Westminster school. In reply, Dr. Bennett A. Coles, an old resident, paid a tribute to his mentors, painting one by one a series of word-pictures which were appreciated as much by the victims as by his other hearers. He intended, as he said, to get his own back—and he did. Dr. Arnold Stott proposing "The Visitors," coupled with the toast the names of Sir Holburt Waring, P.R.C.S., and the Dean of Westminster. He wanted to express gratitude to the two governors present, Mr. Austin Taylor and Lt.-Col. H. C. Bulkeley, who indulged in the kindly practice of providing the hospital, including the sports ground, with machines of all kinds. In welcoming the representative of THE LANCET, Dr. Stott read from an

Mr. H. Morriston Davies: Lung Surgery. (This course is open only to graduates and students of the School.)

SOCIETY FOR THE STUDY OF INEBRIETY.

Tuesday, Oct. 11th.—4 P.M. (at 11, Chandos-street, W.). Dr. J. R. Rees: Psychological Factors in the Prevention and Treatment of Alcohol and Drug Addiction.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

Monday, Oct. 10th, to Saturday, Oct. 14th.—National Hospital for Diseases of the Heart, Westmoreland-street, W. All day course in Cardiology, lectures and démonstrations.—Chelsea Hospital for Women, Arthur-street, S.W. Course in Gynæcology, mornings and/or afternoons.—Metropolitan Hospital, Kingsland-road, E. All day course in General Medicine and Surgery, especially suitable for general practitioners.—St. John's Hospital, Leicester-square, W.C. Afternoon and evening course in Dermatology. Clinical instruction and lectures.—Central London Throat, Nose, and Ear Hospital, Gray's Inn-road, W.C. All day course in Diseases of the Ear, Nose, and Throat.—Royal Albert Dock Hospital, S.E. Week-end Course in Clinical Surgery. Saturday and Sunday all day.—London Light Clinic, Ranelagh-road, S.W. Evening lecture-demonstration in Physical Medicine. Mondays and Wednesdays, 8 to 9 P.M.—These courses are open only to Members of the Fellowship of Medicine.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark-hill, S.E.

Thursday, Oct. 13th.—9 P.M., Dr. W. Sheldon: Nervous Habits in Children.

ROYAL INSTITUTE OF PUBLIC HEALTH, Queen-square, W.C.

Monday, Oct. 10th, and following Tuesday and Wednesday at 4 P.M., Prof. Max Neisser (Frankfort): Some New Investigations Regarding Old Bacteriological Problems. (Harben lectures.)

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, Leicester-square, W.C.

Tuesday, Oct. 11th.—5 P.M., Dr. W. N. Goldsmith: Anatomy and Physiology of the Skin.

Thursday.—5 P.M., Dr. I. Muende: Pathology Demonstration.

MANCHESTER HOSPITAL FOR CONSUMPTION AND DISEASES OF THE THROAT AND CHEST, Hardman-street, Deansgate.

Wednesday, Oct. 12th.—4.30 P.M., Dr. E. R. Clarke: Some Recent Advances in the Diagnosis and Treatment of Pulmonary Tuberculosis.

ANCOATS HOSPITAL, Manchester.

Thursday, Oct. 13th.—Dr. W. J. S. Reid: Anæmias of Chlorotic Type.

MANCHESTER ROYAL INFIRMARY.

Tuesday, Oct. 11th.—4.15 P.M., Mr. P. R. Wrigley: Goitre.

Friday.—4.15 P.M., Mr. J. Morley: Demonstration of Surgical Cases.

Appointments

City of London Maternity Hospital: Lannaman, L. J., L.R.C.P. Lond., M.R.C.S., Senior Resident Medical Officer; Davies, J. O. F., M.B., B.S. Lond., Assistant Resident Medical Officer.

Vacancies

For further information refer to the advertisement columns.

Barry Urban District Council Surgical Hospital.—H.S. At rate of £200.

Beckenham, Bethlem Hospital, Monk's Orchard, Eden Park.—Res. H.P. At rate of £150.

Birmingham, Little Bromwich Hospital for Infectious Diseases.—Jun. Asst. M.O. £300.

Birmingham, Queen's Hospital.—Biochemist. £500.

Bolingbroke Hospital, Wandsworth Common, S.W.—H.S. At rate of £120.

Bradford, Royal Eye and Ear Hospital.—Jun. H.S. £150.

Brentwood, High Wood Hospital for Children.—Asst. M.O. £350.

Cambridge, Addenbrooke's Hospital.—H.P. At rate of £130.

Cancer Hospital, Fulham-road, S.W.—Hon. Neurologist, Hon. Dermatologist, Hon. Gynæcologist. Hon. Ophthalmic Surgeon.

Canterbury, Borough Mental Hospital.—Asst. M.O. £350.

Cheltenham General and Eye Hospitals.—Hon. Surgeon for Ear, Throat, and Nose Diseases.

Chester, East Lancashire Tuberculosis Colony, Barrowmore Hall, Great Barrow.—H.P. At rate of £100.

Chester Royal Infirmary.—H.S. £150.

City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. At rate of £100.

Colindale Hospital, Colindale-avenue, N.W.—Sen. Asst. M.O. £500.

Coventry and Warwickshire Hospital.—Res. H.S. £125.

Durham County Hospital.—Second H.S. £150.

East London Hospital for Children, &c., Shadwell, E.—Asst. Surgeon to Nose, Throat, and Ear Dept. Res. H.P. £125. Also Asst. Physician. £40.

Eastbourne, Princess Alice Memorial Hospital.—H.S. At rate of £150. Also Secretary. £300–£600.

Farnborough Institution Hospital, Kent.—Res. Asst. M.O. £250.

Gloucester County and City Mental Hospital.—Jun. Asst. M.O. £350.

Gloucester, Gloucestershire Royal Infirmary, &c.—Hon. Anæsthetist.

Hampstead General and North-west London Hospital, Haverstock-hill, N.W.—H.S. At rate of £100.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Res. M.O. and H.P. At rate of £150 and £100 respectively.

Hove Hospital.—Res. M.O. £200.

Hull Royal Infirmary.—Asst. Pathologist. 10 gns. per week.

Italian Hospital, Queen-square, W.C.—Hon. Asst. Anæsthetist.

Lancaster Royal Infirmary.—Jun. H.S. At rate of £130.

Leeds Hospital for Women.—H.S. At rate of £100.

Liverpool, County Mental Hospital, Rainhill.—Asst. M.O. £500.

London County Council.—Temporary District M.O.'s. At rate of £156 and £150.

Lowestoft, St. Luke's Hospital.—Sen. Asst. M.O. £500.

Manchester City Education Committee.—Asst. School M.O. £600.

Manchester, Royal Children's Hospital.—Asst. M.O. for Out-patients' Dept. At rate of £150.

Manchester, St. Mary's Hospitals.—Two H.S.'s for Whitworth-street West Hospital. Each at rate of £50.

Medway Institution Hospital, Kent.—Res. Asst. M.O. £250.

Minehead and West Somerset Hospital.—Res. M.O. At rate of £150.

Monmouthshire County Council.—Asst. M.O. £500.

Nottingham, Harlow Wood Orthopædic Hospital.—Asst. to the Surgeon in Charge. £450.

Princess Louise Kensington Hospital for Children, St. Quintin-avenue, W.—Hon. Asst. Surg. to Nose, Throat, and Ear Dept.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Obstetric Surgeon to Out-patients.

Radium Institute, Riding House-street, W.—H.S. At rate of £150.

Reading, Royal Berkshire Hospital.—Res. Anæsthetist. £150.

Rotherham Hospital.—H.P. £180.

Royal National Orthopædic Hospital, 234, Gt. Portland-street, W. Two Registrars. Each £105.

Royal Northern Hospital, Holloway, N.—H.S. At rate of £70.

St. Bartholomew's Hospital, London, E.C.—Asst. Phys.

St. John's Hospital, Lewisham, S.E.—Hon. Anæsthetist.

St. Mary's Hospital, W.—Med. Supt. £400.

St. Mary's Hospital for Women and Children, Plaistow, E.—Res. and Asst. Res. M.O.'s. At rate of £175 and £120 respectively.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—H.S. At rate of £100.

Scarborough Hospital and Dispensary.—Two H.S.'s. Each at rate of £175.

South Shields, Harton Hospital.—H.S. At rate of £150.

Taunton and Somerset Hospital.—H.S. £100.

Torquay, Torbay Hospital.—H.S. £175.

Uxbridge, Hillingdon County Hospital.—Chief Asst. Radiographer. £225.

Violet Melchett Infant Welfare Centre, &c., Wellington-street, Chelsea.—M.O. £50.

West London Hospital, Hammersmith-road, W.—Hon. Anæsthetist. Also Dermatologist and Physician.

Western Ophthalmic Hospital, Marylebone-road, N.W.—Sen. Res. H.S. and Jun. H.S. At rate of £150 and £100 respectively.

Westminster Hospital, Broad Sanctuary, S.W.—Jun. Asst. Pathologist. At rate of £150.

The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Lymm (Chester).

Births, Marriages, and Deaths

MARRIAGES

Jackson—Hallinan.—On Oct. 1st, at the Church of the Holy Cross, Catford, William Eric Jackson, LL.B., Barrister-at-Law, to Eileen Hallinan, M.R.C.S., L.R.C.P., younger daughter of the late J. T. Hallinan, J.P., and Mrs. Hallinan, of Canadian-avenue, Catford.

Millis—Osborne.—On Sept. 29th, at Christ Church, Rathgar, Dublin, Grosvenor Charles Millis, M.C., M.A., M.B., M.R.C.P., to Ruth Henderson, second daughter of the Rev. Dr. Osborne and Mrs. Osborne, of Fairfield House, Rathgar, Dublin.

Rutherfurd—Jackson.—At Kilmacolm Old Kirk, on Sept. 21st 1932, by the Rev. Foster Franklin, M.A., and the Rev. John W. Coutts, M.A., Richard Napier Rutherfurd, B.Sc., A.M.I.C.E., son of the late Henry Rutherfurd, M.A., M.B., C.M., and Mrs. Rutherfurd, 20, Bute-gardens, Glasgow, to Elinor Drinkwater Jackson, F.R.C.S. Edin., elder daughter of Mr. and Mrs. S. Douglas Jackson, Shenvalla, Kilmacolm.

Stewart—Pulman.—On Sept. 28th, at St. Philip's Church, Girlington, Bradford, Henry Hamilton Stewart, M.A., F.R.C.S., to Edna Mary, elder daughter of Mr. and Mrs. Harold H. Pulman, of Hazel Mount, Chellow Dean, Bradford.

DEATHS

Lilley.—On Sept. 29th, Frederic Graham Lilley, L.D.S. R.C.S. Eng., aged 30 years.

Stirling.—On Oct. 1st, at The Lindens, Victoria Park, Manchester, William Stirling, LL.D., D.Sc., M.D., late Brackenbury Professor of Physiology, Victoria University, Manchester, in his 82nd year.

Warliker.—On Sept. 27th, at a nursing-home, after a short illness, Lieut.-Colonel D. P. Warliker (retired), I.M.S., of Wessex Way, Golders Green.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

University of London

The Common Council of the City of London have passed a resolution recommending that £100,000 be given towards the cost of the new University hall.

London Hospital Medical College.—The Schorstein memorial lecture will be delivered in the anatomical theatre of the College at 4.30 P.M. on Thursday, Oct. 13th, by Dr. Otfrid Foerster, professor of neurology in the University of Breslau. His subject will be Dermatomes in Man. Members of the medical profession are invited to attend.

Royal College of Surgeons of England

Demonstrations of museum specimens, for advanced students and medical practitioners, will be given in the theatre of the College at 5 P.M. on Mondays and Fridays, from Oct. 17th to Nov. 7th. The Friday demonstrations will be by Sir Arthur Keith, whose subjects will be: (1) Bone Lesions Produced in Syphilis and in Yaws; (2) the Antiquity of Certain Diseases, particularly of Syphilis; and (3) the Various Forms of Teratoma which Arise in the Notochordal Tract. On Mondays, Oct. 17th and 24th, Mr. C. P. G. Wakeley will deal with Innocent and Malignant Tumours of the Alimentary Tract. Mr. R. Davies-Colley will speak on Intestinal Cysts and Diverticula (Oct. 31st) and on Tumours of the Jaw (Nov. 7th).

West London Medico-Chirurgical Society

The first meeting of the session will be held at the West London Hospital at 8.30 P.M. to-day, Friday, Oct. 7th, when Dr. Julius Burnford will deliver his presidential address entitled: A Therapeutic Survey. The subtitle of the address is: "Fifty million bottles of medicine were issued to nsured persons during the year 1931."

South-West London Medical Society

This society will hold its annual dinner on Wednesday next, Oct. 12th. The first meeting of the session will be held on Oct. 26th, at 8.45 P.M., when Dr. W. Langdon Brown, Regius professor of physic in the University of Cambridge, will deliver an address on Allergy and Some Allergic Diseases. The meetings are held at the Bolingbroke Hospital, Wandsworth.

Fellowship of Medicine and Post-Graduate Medical Association

A course in general medicine and surgery will take place at the Miller General Hospital, Greenwich, from Oct. 17th to 29th. The whole of each day will be occupied with demonstrations, operations, and lectures, and the course is primarily designed for general practitioners. A week-end course in clinical surgery will be given at the Royal Albert Dock Hospital on Saturday and Sunday, Oct. 15th and 16th, occupying the whole of each day with demonstrations, and another, in obstetrics, will take place at the City of London Maternity Hospital on Saturday and Sunday, Oct. 29th and 30th. A weekly course on *Uterine Infections in Obstetrics and Gynæcology* is given at the St. Mary Abbots Hospital, Kensington; not more than four post-graduates may attend any one week. A series of afternoon lectures on renal disease will be given at the Medical Society of London, at 4 P.M. on Tuesdays from Oct. 18th to Dec. 13th; these are free to members of the Fellowship. A panel of teachers, prepared to give clinical instruction, has been formed, and clinics may be attended by arrangement. Further details may be had from the secretary of the Fellowship, at 1, Wimpole-street, London, W.1.

THE SERVICES

ROYAL NAVAL MEDICAL SERVICE

C. J. Waring to be Surg. Lt.

The following appointments are notified: Surg.-Comdrs. A. G. Taylor to *Berwick;* L. F. Strugnell to *Vivid,* for Devonport Barracks; J. L. Priston to *Glorious;* and J. F. Haynes to *Sandhurst.*

Surg. Lt.-Comdr. (D) D. Barker to *Pembroke,* for R.N.B., Chatham.

Surg. Lt. H. D. Plunkett to *Vivid,* for R.N.B., Devonport.

ROYAL ARMY MEDICAL CORPS

Maj. H. J. G. Wells retires on retd. pay.

Capt. T. A. J. M. Dodd retires receiving a gratuity.

Capt. R. Le G. Worsley relinquishes his temp. commn. and is granted the rank of Capt.

INDIAN MEDICAL SERVICE

Lt. E. B. Eedle to be Capt.

Capt. M. N. Khanna relinquishes his temp. commn.

ROYAL AIR FORCE

Flight Lt. R. J. K. Chattey relinquishes his commn. on completion of service.

Medical Diary

SOCIETIES

ROYAL SOCIETY OF MEDICINE, 1, Wimpole-street, W.

MONDAY, Oct. 10th.—4.30 P.M., UNITED SERVICES. Group Captain A. W. Iredell: An Account of Mosquito-proofing Carried Out by the Royal Air Force in India. (Presidential Address.)

FRIDAY.—5.30 P.M., CLINICAL. (Cases at 4.30 P.M.) Mr. Philip Turner: 1. Lumbar Hernia. Mr. Harold Edwards: 2. Sarcoma of Nose with Apparent Cure. Dr. Geoffrey Evans and Dr. R. G. Anderson: 3. Hereditary Ataxia. Dr. F. Parkes Weber: 4. *Persistent Œdema of Right Lower Limb. Other cases will* be shown. 8.30 P.M., OPHTHALMOLOGY. (Cases at 8 P.M.) Mr. A. C. Hudson: Some Surgical Experiences Relative to Disorders of the Lens. (Presidential Address.) Cases: Mr. A. C. Hudson: 1. Arachnodactyly with Dislocated Lenses. 2. Iridotomy for Dislocated Lenses. 3. Sarcoma of Choroid. Mr. Humphrey Neame: 4. Detachment of the Retina treated by Multiple Cautery-puncture, over 5 years' old. *Other cases will be shown.*

MEDICAL SOCIETY OF LONDON, 11, Chandos-street, Cavendish-square, W.

MONDAY, Oct. 10th.—8 P.M., Annual General Meeting: 8.30 P.M., Presidential Address by Sir John Broadbent on Recent Advances in Our Knowledge as to the Ætiology and Treatment of Some of the Acute Infective Fevers.

WEST LONDON MEDICO-CHIRURGICAL SOCIETY.

THURSDAY, Oct. 13th.—3.30 P.M., Sir William Hale-White: Bacilluria.

PADDINGTON MEDICAL SOCIETY.

TUESDAY, Oct. 11th.—9 P.M. (at the Great Western Royal Hotel, Paddington), Mr. A. S. Blundell Bankart: Manipulative Surgery in General Practice.

HARVEIAN SOCIETY OF LONDON.

THURSDAY, Oct. 13th.—8.30 P.M. (at Hammersmith Hospital), Sir H. Gillies: Plastic Surgery.

MEDICAL SOCIETY OF INDIVIDUAL PSYCHOLOGY, 11, Chandos-street, W.

THURSDAY, Oct. 13th.—8.30 P.M., Dr. Seif, of Munich: Opening Address.

LECTURES, ADDRESSES, DEMONSTRATIONS, &c.

LONDON HOSPITAL POST-GRADUATE COURSE.

WEDNESDAY, Oct. 12th.—10.15 A.M., Dr. P. N. Panton: Staphylococcal Infection. 11 A.M., Dr. Donald Hunter: The Treatment of Anæmia. 11.45 A.M., Mr. Hugh Cairns and Dr. W. Russell Brain: Discussion on the Treatment of Head Injuries and their Sequels. 1.30 P.M., Mr. Alan Perry: Subject to be announced later. 2 P.M., Mr. Norman Patterson: Operations. [illegible] 2 P.M., Dr. George Riddoch: [illegible] 2 P.M., Mr. E. C. Lindsay [illegible] 3 P.M., Dr. A. E. Clark-Kenn[illegible]tion: Anasarca and its Treatment. 3 P.M., Dr. Maitland Jones: Demonstration of Cases.

THURSDAY.—10 A.M., Mr. F. Muecke: Practical Points in Diseases of the Ear, Nose, and Throat. 11 A.M., Dr. W. J. O'Donovan: Quackery in Dermatology. 12 A.M., Mr. Hugh Lett: Cystitis. 1.30 P.M., Mr. W. S. Perrin: Anal Fistula. 2 P.M., Dr. John Parkinson: Demonstration of Cases. 2 P.M., Mr. W. Morris: Tonsil Operations. 2 P.M., Mr. Victor Lack and Mr. R. A. Brews: [illegible] 3 P.M., Dr. R. A. Rowlands: War[illegible] Prof. O. Foerster: Schors[illegible] in Man.

FRIDAY.—10 A.M., Mr. R. Milne: The Undependable Knee. 11 A.M., Mr. Eardley Holland: *Indications for* Inducing Abortion. 12 A.M., Dr. Cecil Wall: The Management of Pulm[illegible] 1.30 P.M., Dr. G. Vilvandré: X Ray [illegible].M., Mr. A. J. Walton: Surgical [illegible] Mr. G. E. Neligan [illegible] V. W. Dix: Demons[illegible] P.M., Dr. O. Leyton: Ward [illegible] P.M., Dr. Robert Hutchis[illegible] 5 P.M., Dr. S. P. Bedson [illegible] *Filtrable Viruses and* its Signi[illegible] *Daly: Demonstration* of Methods o[illegible]

SATURDAY.—10 [illegible] Thompson: The Diagnosis of [illegible] A.M., Mr. Russell Howard: W[illegible] 12 A.M., Mr. A. J. Walton: Lec[illegible]n Carcinoma of the Stomach. (This course is for former students of the London Hospital only.)

UNIVERSITY COLLEGE HOSPITAL POST-GRADUATE COURSE.

THURSDAY, *Oct. 13th.—10* A.M., *Dr. F. J. Poynton:* The Dawn of Organic Heart Disease. 11 A.M., Dr. A. M. H. Gray: Eczema. 11 A.M., Mr. Julian Taylor and Dr. K. E. Harris: Demonstration of Cases of Toxic Goitre. 2 P.M., Mr. E. A. Peters: Naso-pharyngeal Sepsis in Relation with Chronic Bronchitis and Emphysema. 3 P.M., Mr. E. K. Martin: Carcinoma of Colon.

FRIDAY.—10 A.M., Sir Thomas Lewis: Fainting Attacks. 11 A.M., Mr. F. J. F. Barrington: *Treatment of Senile Enlargement* of Prostate. 2 P.M., Prof. A. E. *Boycott:* Carcinoma of Lung. 2 P.M., Mr. *Clifford* White: Chronic Pelvic Pain in Women. 3 P.M., Mr. H. Morriston Davies: Lung Surgery. (This course is open only to graduates and students of the School.)

SOCIETY FOR THE STUDY OF INEBRIETY.

TUESDAY, Oct. 11th.—4 P.M. (at 11, Chandos-street, W.). Dr. J. R. Rees: Psychological Factors in the Prevention and Treatment of Alcohol and Drug Addiction.

FELLOWSHIP OF MEDICINE AND POST-GRADUATE MEDICAL ASSOCIATION, 1, Wimpole-street, W.

MONDAY, Oct. 10th, to SATURDAY, Oct. 14th.—NATIONAL HOSPITAL FOR DISEASES OF THE HEART, Westmoreland-street, W. All day course in Cardiology, lectures and démonstrations.—CHELSEA HOSPITAL FOR WOMEN, Arthur-street, S.W. Course in Gynæcology, mornings and/or afternoons.—METROPOLITAN HOSPITAL, Kingsland-road, E. All day course in General Medicine and Surgery, especially suitable for general practitioners.—ST. JOHN'S HOSPITAL, Leicester-square, W.C. Afternoon and evening course in Dermatology. Clinical instruction and lectures.—CENTRAL LONDON THROAT, NOSE, AND EAR HOSPITAL, Gray's Inn-road, W.C. All day course in Diseases of the Ear, Nose, and Throat.—ROYAL ALBERT DOCK HOSPITAL, S.E. Week-end Course in Clinical Surgery. Saturday and Sunday all day.—LONDON LIGHT CLINIC, Ranelagh-road, S.W. Evening lecture-demonstration in Physical Medicine. Mondays and Wednesdays, 8 to 9 P.M.—These courses are open only to Members of the Fellowship of Medicine.

KING'S COLLEGE HOSPITAL MEDICAL SCHOOL, Denmark-hill, S.E.

THURSDAY, Oct. 13th.—9 P.M., Dr. W. Sheldon: Nervous Habits in Children.

ROYAL INSTITUTE OF PUBLIC HEALTH, Queen-square, W.C.

MONDAY, Oct. 10th, and following TUESDAY and WEDNESDAY at 4 P.M., Prof. Max Neisser (Frankfort): Some New Investigations Regarding Old Bacteriological Problems. (Harben lectures.)

LONDON SCHOOL OF DERMATOLOGY, St. John's Hospital, Leicester-square, W.C.

TUESDAY, Oct. 11th.—5 P.M., Dr. W. N. Goldsmith: Anatomy and Physiology of the Skin.

THURSDAY.—5 P.M., Dr. I. Muende: Pathology Demonstration.

MANCHESTER HOSPITAL FOR CONSUMPTION AND DISEASES OF THE THROAT AND CHEST, Hardman-street, Deansgate.

WEDNESDAY, Oct. 12th.—4.30 P.M., Dr. E. R. Clarke: Some Recent Advances in the Diagnosis and Treatment of Pulmonary Tuberculosis.

ANCOATS HOSPITAL, Manchester.

THURSDAY, Oct. 13th.—Dr. W. J. S. Reid: Anæmias of Chlorotic Type.

MANCHESTER ROYAL INFIRMARY.

TUESDAY, Oct. 11th.—4.15 P.M., Mr. P. R. Wrigley: Goitre.

FRIDAY.—4.15 P.M., Mr. J. Morley: Demonstration of Surgical Cases.

Appointments

City of London Maternity Hospital: LANNAMAN, L. J., L.R.C.P. Lond., M.R.C.S., Senior Resident Medical Officer; DAVIES, J. O. F., M.B., B.S. Lond., Assistant Resident Medical Officer.

Vacancies

For further information refer to the advertisement columns.

Barry Urban District Council Surgical Hospital.—H.S. At rate of £200.

Beckenham, Bethlem Hospital, Monk's Orchard, Eden Park.—Res. H.P. At rate of £150.

Birmingham, Little Bromwich Hospital for Infectious Diseases.—Jun. Asst. M.O. £300.

Birmingham, Queen's Hospital.—Biochemist. £500.

Bolingbroke Hospital, Wandsworth Common, S.W.—H.S. At rate of £120.

Bradford, Royal Eye and Ear Hospital.—Jun. H.S. £150.

Brentwood, High Wood Hospital for Children.—Asst. M.O. £350.

Cambridge, Addenbrooke's Hospital.—H.P. At rate of £130.

Cancer Hospital, Fulham-road, S.W.—Hon. Neurologist, Hon. Dermatologist, Hon. Gynæcologist. Hon. Ophthalmic Surgeon.

Canterbury, Borough Mental Hospital.—Asst. M.O. £350.

Cheltenham General and Eye Hospitals.—Hon. Surgeon for Ear, Throat, and Nose Diseases.

Chester, East Lancashire Tuberculosis Colony, Barrowmore Hall, Great Barrow.—H.P. At rate of £100.

Chester Royal Infirmary.—H.S. £150.

City of London Hospital for Diseases of the Heart and Lungs, Victoria Park, E.—H.P. At rate of £100.

Colindale Hospital, Colindale-avenue, N.W.—Sen. Asst. M.O. £500.

Coventry and Warwickshire Hospital.—Res. H.S. £125.

Durham County Hospital.—Second H.S. £150.

East London Hospital for Children, &c., Shadwell, E.—Asst. Surgeon to Nose, Throat, and Ear Dept. Res. H.P. £125. Also Asst. Physician. £40.

Eastbourne, Princess Alice Memorial Hospital.—H.S. At rate of £150. Also Secretary. £300–£600.

Farnborough Institution Hospital, Kent.—Res. Asst. M.O. £250.

Gloucester County and City Mental Hospital.—Jun. Asst. M.O. £350.

Gloucester, Gloucestershire Royal Infirmary, &c.—Hon. Anæsthetist.

Hampstead General and North-west London Hospital, Haverstock-hill, N.W.—H.S. At rate of £100.

Hospital for Epilepsy and Paralysis, Maida Vale, W.—Res. M.O. and H.P. At rate of £150 and £100 respectively.

Hove Hospital.—Res. M.O. £200.

Hull Royal Infirmary.—Asst. Pathologist. 10 gns. per week.

Italian Hospital, Queen-square, W.C.—Hon. Asst. Anæsthetist.

Lancaster Royal Infirmary.—Jun. H.S. At rate of £130.

Leeds Hospital for Women.—H.S. At rate of £100.

Liverpool, County Mental Hospital, Rainhill.—Asst. M.O. £500.

London County Council.—Temporary District M.O.'s. At rate of £156 and £150.

Lowestoft, St. Luke's Hospital.—Sen. Asst. M.O. £500.

Manchester City Education Committee.—Asst. School M.O. £600.

Manchester, Royal Children's Hospital.—Asst. M.O. for Out-patients' Dept. At rate of £150.

Manchester, St. Mary's Hospitals.—Two H.S.'s for Whitworth-street West Hospital. Each at rate of £50.

Medway Institution Hospital, Kent.—Res. Asst. M.O. £250.

Minehead and West Somerset Hospital.—Res. M.O. At rate of £150.

Monmouthshire County Council.—Asst. M.O. £500.

Nottingham, Harlow Wood Orthopædic Hospital.—Asst. to the Surgeon in Charge. £450.

Princess Louise Kensington Hospital for Children, St. Quintin-avenue, W.—Hon. Asst. Surg. to Nose, Throat, and Ear Dept.

Queen Charlotte's Maternity Hospital, Marylebone-road, N.W.—Obstetric Surgeon to Out-patients.

Radium Institute, Riding House-street, W.—H.S. At rate of £150.

Reading, Royal Berkshire Hospital.—Res. Anæsthetist. £150.

Rotherham Hospital.—H.P. £180.

Royal National Orthopædic Hospital, 234, Gt. Portland-street, W. [illegible]

Roy [illegible] *ay, N.*—H.S. At rate of £70.

St. [illegible] *on, E.C.*—Asst. Phys.

St. [illegible] *S.E.*—Hon. Anæsthetist.

St. [illegible] Supt. £400.

St. [illegible] *and Children, Plaistow, E.*—Res. and Asst. Res. M.O.'s. At rate of £175 and £120 respectively.

Samaritan Free Hospital for Women, Marylebone-road, N.W.—H.S. At rate of £100.

Scarborough Hospital and Dispensary.—Two H.S.'s. Each at rate of £175.

South Shields, Harton Hospital.—H.S. At rate of £150.

Taunton and Somerset Hospital.—H.S. £100.

Torquay, Torbay Hospital.—H.S. £175.

Uxbridge, Hillingdon County Hospital.—Chief Asst. Radiographer. £225.

Violet Melchett Infant Welfare Centre, &c., Wellington-street, Chelsea.—M.O. £50.

West London Hospital, Hammersmith-road, W.—Hon. Anæsthetist. Also Dermatologist and Physician.

Western Ophthalmic Hospital, Marylebone-road, N.W.—Sen. Res. H.S. and Jun. H.S. At rate of £150 and £100 respectively.

Westminster Hospital, Broad Sanctuary, S.W.—Jun. Asst. Pathologist. At rate of £150.

The Chief Inspector of Factories announces a vacant appointment for a Certifying Factory Surgeon at Lymm (Chester).

Births, Marriages, and Deaths

MARRIAGES

JACKSON—HALLINAN.—On Oct. 1st, at the Church of the Holy Cross, Catford, William Eric Jackson, LL.B., Barrister-at-Law, to Eileen Hallinan, M.R.C.S., L.R.C.P., younger daughter of the late J. T. Hallinan, J.P., and Mrs. Hallinan, of Canadian-avenue, Catford.

MILLIS—OSBORNE.—On Sept. 29th, at Christ Church, Rathgar, Dublin. Grosvenor Charles Millis, M.C., M.A., M.B., M.R.C.P., to Ruth Henderson, second daughter of the Rev. Dr. Osborne and Mrs. Osborne, of Fairfield House, Rathgar, Dublin.

RUTHERFURD—JACKSON.—At Kilmacolm Old Kirk, on Sept. 21st 1932, by the Rev. Foster Franklin, M.A., and the Rev. John W. Coutts, M.A., Richard Napier Rutherfurd, B.Sc., A.M.I.C.E., son of the late Henry Rutherfurd, M.A., M.B., C.M., and Mrs. Rutherfurd, 20, Bute-gardens, Glasgow, to Elinor Drinkwater Jackson, F.R.C.S. Edin., elder daughter of Mr. and Mrs. S. Douglas Jackson, Shenvalla, Kilmacolm.

STEWART—PULMAN.—On Sept. 28th, at St. Philip's Church, Girlington, Bradford, Henry Hamilton Stewart, M.A., F.R.C.S., to Edna Mary, elder daughter of Mr. and Mrs. Harold H. Pulman, of Hazel Mount, Chellow Dean, Bradford.

DEATHS

LILLEY.—On Sept. 29th, Frederic Graham Lilley, L.D.S. R.C.S. Eng., aged 30 years.

STIRLING.—On Oct. 1st, at The Lindens, Victoria Park, Manchester, William Stirling, LL.D., D.Sc., M.D., late Brackenbury Professor of Physiology, Victoria University, Manchester, in his 82nd year.

WARLIKER.—On Sept. 27th, at a nursing-home, after a short illness, Lieut.-Colonel D. P. Warliker (retired), I.M.S., of Wessex Way, Golders Green.

N.B.—A fee of 7s. 6d. is charged for the insertion of Notices of Births, Marriages, and Deaths.

NOTES, COMMENTS, AND ABSTRACTS

THE MEDICAL QUARTER[1]

THE medical quarter of London, as Cavendish-square and the surrounding streets are termed here, is described in detail by Dr. Bryan, an outline map illustrating well the development of the district. The ownership of "the manor and parish, in the Hundred of Ossulston, Middlesex, anciently called Tyburn," has had many interesting vicissitudes. Renamed Marylebone, from the Church of St. Mary (not Mary-the-Good, but Mary-at-Burn), it was acquired in the sixteenth century by Henry VIII. from one Hotson, leased by Queen Elizabeth to the Forsyth family, reacquired by James I., pawned by Charles II., seized by Cromwell, and reseized by Charles II. But James I. had sold the Harley-street area back to the Forsyths, from whom it passed by marriage settlement to the Austin family. The Austins sold their property in the reign of Queen Anne to John Holles, a commoner who had married the only child of the Duke of Newcastle, and had been granted the title of his father-in-law, apparently because he was very rich. But Holles had no son, and the property passed to his daughter, Lady Henrietta Cavendish Holles, who married Edward Harley, Earl of Oxford of a new creation, and owner of the Wigmore estate in Hertfordshire, and of the Wimpole estate in Cambridgeshire. Again the property devolved on an only daughter, who married William Bentinck, Duke of Portland, owner of Welbeck Abbey, and a follower of William III. The spendthrift Duke of Chandos acquired the site whereon Chandos-street is built, having one wing of the unfinished Chandos House upon it, while Langham-place and the Langham Hotel are named after Sir John Langham, who built the hotel. The nomenclature of the estate planned by the Portland family is thus comprehensively explained.

In 1720, when Cavendish-square was first laid out, a Dr. James Newton came there to practice, and towards the end of the century we find the famous Matthew Baillie residing there, but it was not until the end of the first quarter of the nineteenth century that the square and three or four streets in its immediate vicinity became a recognised centre for medical consultants, rapidly emptying the famous City centre, Finsbury-square. Since then the names of the medical residents in the area read like a roll-call of successful London doctors; and even more than the square itself, Harley-street, Wimpole-street, Queen Anne-street, and Portland-place keep up the historic connexion with medicine.

Dr. Bryan supplies many interesting biographical notes upon celebrated or notorious residents "round about Harley-street" since the estate was built. With such a varied choice before him among the doctors it is inevitable that his selection for notice should seem capricious, but what he has to say is amusing and substantially accurate. Many of our readers will be interested in the book.

TIMELY AIDS TO THE NEW PHARMACOPŒIA

The twentieth edition of Martindale and Westcott's "Extra Pharmacopœia" (London: H. K. Lewis and Co., Vol. I. Pp. 1216. 27*s.* 6*d.*) just issued gives in a synopsis the principal editions and changes to be effected in the B.P. 1932, as was done on previous occasions (1885, 1898, 1914) when a new edition was brought out. Many of the older preparations will, Mr. Martindale thinks, continue in favour and are accordingly retained with the note (B.P. '14.) —To help in understanding the British Pharmacopœia, 1932, which was first issued for sale on Saturday last, Mr. H. Wippell Gadd, formerly lecturer on pharmacy at the University College, Exeter, has brought out a twelfth edition of his well-known Synopsis (London: Baillière, Tindall and Cox. Pp. 189. 2*s.* 6*d.*), which contains a summary of its requirements for daily reference. The articles and preparations removed from the B.P. 1914 number over 300; all the decoctions have gone, several of the extracts, many of the tinctures and syrups, and there are now no official medicinal wines. A list is given of the principal drugs and preparations of which the composition or the strength has been altered. In addition to its regular features, the Synopsis contains a summary of the Dangerous Drugs Acts, 1920–1932.—A free copy of the B.D.H. Guide to the B.P., 1932, may be obtained on application to the British Drug Houses, Ltd. (Graham-street, City-road, London, N.1), in which attention is directed especially to the preparations which differ materially from the corresponding preparations of the B.P., 1914. Throughout the Guide, which contains 122 large and well printed pages, single and double rules clearly indicate substances which are official for the first time and those which are altered.—Messrs. Woolley Sons and Co., Ltd., of Manchester, have also issued a pamphlet of 83 pages containing the alterations, additions, and deletions in the new Pharmacopœia in a form that will allow of easy reference by pharmacists and medical practitioners.

NEW PREPARATIONS

MULTIBRAL (Messrs. H. R. Napp, Ltd., 3 and 4, Clement's-inn, Kingsway, London, W.C.)—We have received a sample of this preparation of sodium monobromoleate, for which the claim is made that it gives an intensive bromine action 20 times greater than bromides, while it is free from secondary toxic affections. The use of multibral is recommended in conditions of nervous excitability as well as in organic diseases where bromide is customarily prescribed, while the regulation of the dosage is left to the directions of the practitioner.

BOURN-VITA.—This preparation, manufactured by Messrs. Cadbury Bros. Ltd., Bournville, is recommended as a specially palatable method of obtaining the benefits derived from the ingestion of milk, eggs, and cocoa. The preparation contains a large percentage of malt, and as it is easily digested as well as restorative, the manufacturers recommend it specially as "a good-night drink."

SCIATAGO.—This drug, supplied in dragées by Messrs. Coates and Cooper, Ltd. (94 Clerkenwell-road, London, E.C.), combines Phenyl-Quinolin-Carboxylic Acid, Hexamethylene-tetramine and Glycocoll, and is a new attempt to meet the painful symptoms associated with rheumatism, and the myalgic and neuralgic conditions falling under the general headings of lumbago and sciatica, with their associated fibrositis pleurodynia, and other manifestations. The dragée is prepared in accordance with the view that these pathological conditions owe their origin to a deranged metabolism, and the manufacturers claim that they have received clinical testimony that the relief of "rheumatismal affections of the most varied description" has been gratifying. Upon the tin in which the dragées are distributed it is indicated that two may be taken twice daily after meals, but it is advised that they should be used in accordance with the directions of the doctor.

The Glaxo Laboratories (56, Osnaburgh-street, London, N.W.) have sent us a specimen case of AMPOULES, with a price list of the various preparations which can be employed through their medium. The distinctive feature of the ampoules is that they open with a clean break and have no dead space in which part of the solution may accumulate. The firm believe that their prices are 25 per cent. lower than those generally prevalent for such products, economies being secured not only by control of production and distribution of costs, but by the employment of a simple packing. The exact place of breaking the ampoule is indicated in the instructions, and the use of the opener which is supplied is described clearly.

ADDRESSES AND ORIGINAL ARTICLES

THE ESTABLISHMENT OF IMMUNITY IN SOME INFECTIOUS FEVERS*

BY SIR JOHN BROADBENT, BART., M.D. OXF., F.R.C.P. LOND.

CONSULTING PHYSICIAN TO ST. MARY'S HOSPITAL, AND PHYSICIAN TO THE LONDON FEVER HOSPITAL

I MUST first of all thank you for the honour you have done me in electing me your President. It is just 41 years since my father held the same distinguished position, and I am proud that something of his mantle should have fallen on me, though I am conscious how unworthy a successor I am.

I have chosen for my address the treatment of infectious fevers, as for over 25 years I have been on the staff of the London Fever Hospital.

Diphtheria

In 1893, when I was house physician at St. Mary's Hospital, it fell to my lot to have to perform 20 out of 46 tracheotomies on young children admitted to the isolation ward for urgent laryngeal diphtheria. Of the 46 cases 31 died, a mortality of over 62 per cent., and no child under 3 recovered. Early in the following year my brother had a severe attack of diphtheria which nearly proved fatal, followed by extensive paralysis which laid him up for over three months. In those days the only treatment for diphtheria was swabbing the throat with some strong antiseptic which had little or no effect in arresting the growth of the bacillus, so that the mortality was high, and complications were very common. I will outline the revolutions in treatment briefly, not discussing them, but dwelling only on the results.

Klebs, in 1875, described the diphtheria bacillus, which he isolated from the membrane on affected throats. It was cultured and identified as the organism responsible for diphtheria by Löffler in 1884. In 1890 Behring discovered that the serum of horses immunised against diphtheria neutralised the diphtheria toxin, and when injected into guinea-pigs conferred protection upon them. In 1894 Roux, working at the Pasteur Institute, demonstrated the value of this specific antitoxin for purposes of treatment in human beings. In September of that year, together with Martin, he published an epoch-making paper in the *Annales de l'Institut Pasteur*, describing the successful results obtain by treatment of 300 children suffering from diphtheria by injecting antitoxin, the mortality being reduced by nearly 50 per cent. From 1895 onwards the use of antitoxin became general, and the following statistical table taken from the report of the Metropolitan Asylums Board for 1929 is an example of the great decrease in mortality from diphtheria which resulted in this country and throughout the world from the employment of antitoxin.

M.A.B. Statistics: Diphtheria Mortality

Year.	Admissions.	Mortality per 100 of patients treated.	
1885–1889	821	39 1	Before use of antitoxin.
1890–1894	10,777	29 8	
1895–1899	29,058	17·0	
1900–1904	31,819	10 8	
1927	9,155	4 0	
1928	8,981	3 7	

It has been found essential that the antitoxin should be given as soon as possible, and if administered within the first 24 hours in sufficient doses there should be little risk of death for the patient. The later the serum is given, the less its efficacy. The following table compiled by Dr. J. D. Rolleston from a series of 1500 cases of diphtheria treated by antitoxin is quoted in his book "The Acute Infectious Diseases."

Antitoxin administered.	Total of cases.	Deaths.	Mortality per 100.
1st day	62	0	0
2nd day	324	10	3·08
3rd day	391	24	6·1
4th day	309	33	10·6
5th day and later	414	49	11·5

In 1913 the skin reaction test indicative of whether or no the subject is immune to diphtheria was discovered by Schick. This consists of injecting intradermally a small measured dose of diphtheria toxin diluted with normal saline. If the subject is not immune a positive reaction occurs within 24 hours which consists of a circumscribed area of redness with some infiltration of the skin. This becomes more intensive in four to five days, leaving a brownish pigmentation as it fades. A negative reaction shows that the patient is not susceptible to diphtheria.
